APPENDIX

TO THE

REPORT OF THE MINISTER OF AGRICULTURE

ON

EXPERIMENTAL FARMS.

---o---

OTTAWA, 1st December, 1898.

SIR,—I beg to submit for your approval the twelfth annual report of the work done and in progress at the several Experimental Farms.

In addition to the duties devolving on me as Director of the Experimental Farms, I have also continued to carry on the work of the Agriculturist and have prepared for the present report particulars of the results of the experiments conducted at the Central Experimental Farm with field crops and stock. You will also find appended reports from the following officers of the Central Experimental Farm: From the Horticulturist, Mr. W. T. Macoun; from the Chemist, Mr. Frank T. Shutt, and from the Entomologist and Botanist, Dr. James Fletcher. Reports are also submitted from the Poultry Manager, Mr. A. G. Gilbert.

From the Branch Experimental Farms there are reports from Mr. R. Robertson. Superintendent, and from Mr. W. S. Blair, Horticulturist of the Experimental Farm for the Maritime Provinces, at Nappan, Nova Scotia; from Mr. S. A. Bedford, Superintendent of the Experimental Farm for Manitoba, at Brandon; from Mr. Angus Mackay, Superintendent of the Experimental Farm for the North-west Territories, at Indian Head; and from Mr. Thos. A. Sharpe, Superintendent of the Experimental Farm for British Columbia, at Agassiz.

In these reports there will be found the results of many important and carefully conducted experiments in agriculture, horticulture and arboriculture, the outcome of practical work in the fields, barns, dairy and poultry buildings, orchards and plantations at the several experimental farms; also of scientific investigations in the chemical laboratory and the information gained from the careful study of the life histories and habits of injurious insects and the methods by which noxious weeds are propagated and spread, together with the most practical and economical measures for their destruction.

In the report of the Entomologist and Botanist there will also be found particulars of the experiments and observations made during the past year in connection with the Apiary.

The large and constantly increasing demand by the farmers of the Dominion for the publications issued from the experimental farms is a gratifying evidence of the desire for information among this class of the community, also of the high esteem in which these records of the work of the farms are held. It is hoped that the facts brought together in the present issue will be found of much practical value to the Canadian farmer and fruit grower and that they may assist in advancing agriculture and horticulture in this country.

I have the honour to be, sir,

Your obedient servant,

WM. SAUNDERS,

Director Experimental Farms.

To the Honourable

The Minister of Agriculture,

Ottawa.

ANNUAL REPORT

ON THE

EXPERIMENTAL FARMS

REPORT OF THE DIRECTOR AND ACTING AGRICULTURIST.

(*WM. SAUNDERS, LL.D., F.R.S.C., F.L.S.*)

In submitting the twelfth annual report of the work done on the Central and Branch Experimental Farms, attention is called to the steady extension of the operations undertaken and to the multiplicity of the details involved. In the planning of the different series of experiments to be undertaken, new material is added from year to year, and their scope is constantly widening. During 1898 the Experimental Farms have shared in the general success which has attended agricultural operations throughout Canada, and good crops have been harvested at all the farms excepting that for the Maritime Provinces, the harvest has brought returns well above the average, while at Nappan, Nova Scotia, where the climatic conditions were less favourable, the crops may be said to have given a fair average yield.

With the growing interest manifested in the mission and work of these farms, many inquiries are made from time to time as to the agricultural conditions existing prior to their establishment, also as to the size and location of each farm, the character of the land, and the area under cultivation. Many particulars are also sought in reference to the general objects in view in the conduct of the work and the progress made along different lines at each farm. To give such inquirers the information sought, brief reference will here be made to the state of agriculture in Canada during the earlier history of this country and some particulars presented regarding each of the Experimental Farms.

AGRICULTURE IN CANADA IN EARLIER TIMES.

It had long been recognized by the more thoughtful part of the community that the early practice of farming in Canada had been wasteful. It had consisted mainly of efforts to take all that could be conveniently got from the land in crops without returning any sufficient equivalent. Such methods had resulted in exhaustion, which although fortunately not complete was so far accomplished that large areas of land in different parts of the early settled portions of the country on which fine crops of wheat had been grown for many years had ceased to give satisfactory returns, and had been abandoned to pasture and other purposes, while new fields had been sought for the cultivation of this valuable cereal so necessary for man's sustenance.

Until recent times it had not been generally understood that every crop grown takes from the land on which it has been produced, certain ingredients known as plant food, and that where repeated drafts are made on this store of nutrition, without making corresponding returns, such soil, no matter how fertile it may have been, will sooner or later, become so far exhausted as to cease to produce profitable crops.

Fortunately the stores of fertility in good soil are large, and are mainly held in insoluble forms, which can only be brought into soluble and available conditions very gradually. To bring this about the conditions must be favourable. The land must be diligently worked, to expose the component parts in turn to the action of air and sunshine which promote the growth of certain ferments and bacterial forms, which take an active part in this transformation. Wasteful farming is almost always associated with a negligent treatment of the land, ploughing being scanty, cultivation practically abandoned, and the crops largely left to take care of themselves. Under such treatment nature refuses to open her stores of fertility and the indolent farmer realizes such small returns, that farming with him soon ceases to be a paying occupation. When an industrious and careful occupant comes into possession of such a worn out farm and ploughs deeply and cultivates often, gives regular dressings of reasonable quantities of manure, and otherwise adds to the fertility of the land by the occasional ploughing under of green crops of clover, and further follows a judicious rotation of crops, the fertility of such land will soon be so far restored that the toil of the husbandman will receive a liberal reward.

CONDITION OF AGRICULTURE IN THE LAST DECADE.

Early in the last decade agriculture in Canada was very much depressed. In 1884 the House of Commons appointed a special commission to inquire into this important industry and to suggest means for its advancement. Evidence was taken from experts in different parts of the country and opinions obtained from many practical farmers. The general opinion was to the effect that farmers were much in need of information in reference to many branches of their calling, and that agriculture in Canada might be much advanced if some means were adopted whereby the farmer might be instructed how best to overcome the difficulties which surround his occupation, by practical demonstrations and the free circulation of suitable literature; and as a means to this end the establishment of Experimental Farms was recommended.

ESTABLISHMENT OF EXPERIMENTAL FARMS IN CANADA.

No action was taken on this suggestion until the latter part of 1885, when Sir John Carling, who had been recently appointed Minister of Agriculture, took steps to bring about the organizing of these institutions in Canada. Inquiries were made as to the methods adopted in working experimental farms and stations in other countries and the writer was instructed to visit a number of such institutions then existing, to prepare a report and to make recommendations as to the form which it seemed most desirable this work should assume in this country. This report was prepared and distributed to Parliament in February, 1886, when an Act was introduced and passed with the concurrence of both sides of the House authorizing the Government to establish a Central Experimental Farm and four Branch Experimental Farms in different parts of Canada.

With the appointment of the Director in October, 1886, the work was begun. Sites for the farms were chosen, officers were appointed and most of the farms were fairly well equipped within two years from that date and all doing good work in their respective spheres of usefulness.

IMPORTANT LINES OF WORK UNDERTAKEN.

Since the primary object in the establishment of these farms was to assist the farmer in his endeavours to overcome the difficulties attendant on his work and to adopt such measures as were likely to result in making farming in this country more profitable, much attention was given from the beginning to those subjects which lie at the foundation of successful agriculture. Among the most important of these are the maintaining of the fertility of the soil, so as to provide for a succession of good crops without

exhaustion; the determining of the best methods of preparing the land for different crops in the several climates of the Dominion; the finding out the best time for the sowing of seed and the ascertaining by repeated tests which are the most profitable varieties of grain, fodder plants and roots to grow, taking into consideration productiveness, quality and earliness of ripening.

SATISFACTORY PROGRESS MADE.

During the past eleven years a wonderful change has taken place in the methods of farming in this country. Instead of selling the coarse grains and thus shipping away the plant food which these crops have taken from the land, a very large proportion of these, associated with suitable fodders, are now fed to cattle, swine and sheep and are thus converted into dairy products, beef, pork, and mutton; and by this method a large part of the fertility taken from the land by the crops has been restored to the soil in the manure. The great value of barn-yard manure is now generally recognized: it is much better cared for, and the most economical methods of handling and using it are more generally practised. The practical lessons taught by the experiments which have been conducted at the Experimental Farms, have been turned to a useful account and much solid advancement has been made.

In the meantime the occupation of farming has been elevated in the eyes of the community. It is no longer looked upon as a sort of drudgery, suited to the dull and slow-going, but is now regarded as a suitable field for the higher intelligence of more cultivated minds. It is recognized as a calling requiring much skill to conduct it successfully and as giving ample scope for the exercise of the most active and earnest minds, and one in which information of almost every sort may be turned to practical account. A few figures will illustrate the progress which has been made along the lines referred to. In 1884 the value of the cheese exported from Canada was $7,251,989; in 1898 it was $17,572,763. During the same period the value of the butter exported has nearly doubled. The exports of cattle have also increased considerably, while the trade in pork has made a phenomenal growth. In 1884 the value of the exports of hams, bacon, pork and lard was less than one million dollars; in 1898 they amounted to more than 8 million dollars.

CENTRAL EXPERIMENTAL FARM.

Many useful lines of work have been carried on at each of the Experimental Farms, but the larger part of the special work of investigation has been done at the Central Farm. As this institution was intended to serve the purposes of a central bureau of information and to meet the requirements of the two most important provinces, Ontario and Quebec, a site was chosen near the boundary line between these provinces where the climate fairly represents the larger part of their area. This farm is located at Ottawa about three miles from the Parliament buildings and consists of 465 acres in all, which is divided by a public road, 400 acres lying to the west and 65 acres to the east of that road. On the 400 acres the buildings are located, which include an office building and museum and a chemical laboratory. A large barn consisting of a central portion, and two wings, with silos at one end having capacity for 350 tons of ensilage. The lower story of this building being on a level with the barn-yard affords accommodation for a considerable number of cattle, while one of the wings is occupied by the pure bred bulls and the other with the working horses. There is also a piggery, a dairy building and poultry-houses; also a sheep building in process of construction. An implement shed, granary and tool-house, a large root-house, and a conservatory with houses for seed testing and seed distribution. There are also several dwellings used as residences by some of the officers and men in charge of the several branches of the work. The soil of this farm varies much in its character in different parts, some portions are heavy clay loam, some a friable clay loam with more or less sand intermixed. The larger part, however, consists of varying

qualities of sandy loam ranging from a heavy loam to one of a light character. About 328 acres of this land is devoted to farming purposes and experiments with farm crops, 42 acres to the testing of fruits and vegetables, 20 acres to the growing of timber trees and about 10 acres to the buildings and the plantations about them of ornamental trees shrubs and plants, sample hedges, &c.

ARBORETUM AND BOTANIC GARDEN.

The 65 acres on the east side are devoted to the purposes of an Arboretum and Botanic Garden where economic and ornamental trees, shrubs and plants have been brought together from all countries with cold or temperate climates, where they are tested side by side and their hardiness and usefulness determined. The plantations of trees and shrubs now include nearly 2,500 species and varieties and about 1,100 varieties of perennial plants are growing in the borders devoted to this purpose. In the orchards about 1,200 varieties of fruits are under test, while the trial plots and fields of grain, fodder crops and roots, include a very large number of different sorts gathered from many distant countries and supplemented by many promising varieties which have been produced on the experimental farms by cross-fertilizing and selection.

PRODUCTION OF NEW VARIETIES OF CEREALS.

Among the many lines of scientific investigation carried on at the Central Farm none have attracted more general attention than the work done in the production of new varieties of cereals by cross-fertilizing and hybridizing. Since the Experimental Farms were established more than 700 new sorts have been so produced. Some of the varieties of grain used as a basis for this work have been brought from the northern parts of Russia, others from high altitudes in the Himalaya Mountains in India. In these localities some of the earliest ripening varieties of grain are found. These have been crossed with standard sorts of the highest quality and productiveness with the object of producing new varieties combining the high quality and productiveness of the one parent with the earliness of the other.

After careful test all those of less promise are rejected, but there are still under trial more than 200 varieties of these hybrid and cross-bred sorts consisting of wheat, barley, oats and pease. Some of these new kinds have produced heavy crops for several years past and seem likely to occupy a prominent place among the best sorts in cultivation. Many new fruits have been similarly produced, especially of hardy varieties likely to be useful in the Canadian North-west.

DIVISION OF WORK.

The Director, who supervises the work of all the Experimental Farms, resides at the Central Farm but makes personal inspection of the branch farms at least once a year. For several years past the Director has also carried on the agricultural work at the Central Farm, such as the field experiments with cereals, fodder crops and roots, and the feeding experiments with steers, milch cows and swine, also the work of the dairy. Associated with the Director are the following officers :—

The Horticulturist who takes charge of the experiments with fruits and vegetables and acts as Curator of the Arboretum.

The Chemist, who makes analyses of grasses and other fodder crops to ascertain their feeding value at different periods in their growth. He also analyses soils and fertilizers and determines the purity of water supplies on farms, and conducts much other useful chemical work bearing on agriculture.

The Entomologist and Botanist, who carries on investigations in reference to injurious and beneficial insects and noxious weeds and tests the value and usefulness of many native and imported grasses for hay and pasture, also the relative merits of other fodder plants. Experiments are also conducted under this officer in bee keeping.

View of part of Shrubbery on the Central Experimental Farm at Ottawa, Ontario.

The Poultry Manager, who carries on experiments with many different breeds of fowls to find out the best sorts as egg layers, and the best for table use, also the most satisfactory crosses for rapid growth and early laying, and the best and most economical methods of feeding.

There is also a Farm Foreman who directs the labour of the workmen and teams, an Accountant and a suitable office staff for conducting the large correspondence, both in English and French, which is carried on with farmers in all parts of the Dominion.

The barns are well supplied with milch cows and steers suitable for the carrying on of experiments relating to the production of milk and beef. Some useful pure-bred bulls are kept at this farm for breeding purposes, and for the improvement of stock in the district. The piggery contains a good selection of animals, representing the most useful breeds of swine. Many experiments are carried on each year in the breeding and feeding of these different classes of animals, and the information gained by these tests has been of much practical value to the farming community.

EVIDENCE OF PROGRESS.

Evidence of the progress made in the growing of farm crops under the improved methods adopted at the Central Experimental Farm at Ottawa is furnished by a comparison of the average yields of grain obtained during the early years with those of more recent ones. The years 1889, 1890 and 1891, the three first after this farm was fairly established, when compared with 1896, 1897 and 1898, show the following results:—

	1889-90-91. Per acre.		1896-97-98. Per acre.		Gain in recent years. Per acre.	
	Bush.	lbs.	Bush.	lbs.	Bush.	lbs.
Oats, average crop for three years	32	17	56	6	23	13
Barley " "	31	6	43	13	12	7
Wheat " "	15	19	20	9	4	50

These additions in the crop have been gained by a moderate use of fertilizers, and the ploughing under of green crops, the more thorough working of the land, early sowing and the selection of more productive varieties for seed. All these factors have assisted in bringing about this gratifying result. The number of varieties under test in the early years averaged as follows: oats, 28; barley, 23; spring wheat, 28; in the later years, oats, 62; barley, 34, and spring wheat, 39.

When we consider that the addition of one bushel of each of the three cereals named to the average crop of the province of Ontario alone, would add nearly one million dollars to the earnings of the farmers, the significance of these figures becomes apparent.

EXPERIMENTAL FARM FOR THE MARITIME PROVINCES.

This branch farm, designed to serve the purposes of the three Maritime Provinces, Nova Scotia, New Brunswick and Prince Edward Island, was located at Nappan, in the County of Cumberland, N.S., on the Intercolonial Railway, about eight miles east of the boundary line between New Brunswick and Nova Scotia, and easily accessible from Prince Edward Island. Its distance from the Central Farm at Ottawa is 743 miles.

About 310 acres are included in this farm, of which nearly 100 acres is covered with wood. The cleared land may be classified approximately as follows: Marsh or dyke land, valuable for the growth of hay, 50 acres; interval or lower upland, 50 acres, and higher upland, 110 acres. The higher land faces the west, and overlooks the inlet from the Bay of Fundy, and commands a good view of the surrounding country. The soil of this farm fairly represents the better class of farms on the border line of the two provinces, and for a long distance on either side. It is chiefly clay loam, more or less

mixed with sand, becoming heavy or light as clay or sand predominates, with some parts gravelly, and having a subsoil varying from clay to gravelly clay. The advantages embodied in this location include variety of soil, partial shelter from prevailing winds, a central location and nearness to the main line of travel.

WORK UNDERTAKEN.

Work was begun on this farm in the spring of 1887, Mr. Wm. M. Blair acting as Superintendent. Under his management the farm was much improved. A large area of land was drained, and the great value of underdraining in the Maritime Provinces demonstrated. Much useful experimental work has been carried on with grain, roots, grasses, Indian corn and other fodder crops, orchards have been planted, and belts and clumps of ornamental trees and shrubs placed so as to act as wind-breaks and to ornament the grounds around the buildings. Suitable buildings have been provided for carrying on the work, including a large barn, a stable, piggery, poultry building and an implement shed, also residences for the Superintendent, Horticulturist and herdsman.

CHANGES IN STAFF.

In 1896, after nine years of useful service, Mr. Wm. M. Blair resigned his position as Superintendent, and Mr. Geo. W. Forrest was appointed as his successor. Mr. W. S. Blair acting as Horticulturist. Mr. Forrest remained in office one year, when on his resignation the present Superintendent, Mr. R. Robertson, received the appointment. Since Mr. Robertson took office, further improvements have been made in the farm buildings, the area of cleared land has been increased and the dairy herd much improved by the purchase of a number of excellent milking cows. The production of milk throughout the year for dairy purposes has become a prominent feature in the work of this farm. Some further experiments have also been conducted in the fattening of steers. The instructive tests made under the former superintendents in the growing of cereals have been continued, and much attention given to the growing of fodder plants, grasses, roots and potatoes for the production of which the climate is favourable.

HORTICULTURAL BRANCH.

In the horticultural branch, many new varieties of fruit have been added to those under test. A large number of experiments have been conducted with vegetables and further additions made to the ornamental trees, shrubs and plants under trial at this farm.

EXPERIMENTAL FARM FOR MANITOBA.

The Experimental Farm organized for the benefit of the farmers of this province is located at Brandon, which is 132 miles west of Winnipeg and 78 miles east of the Manitoba boundary. The distance from the Central Farm at Ottawa is 1,437 miles. This farm is about 1½ miles from the city of Brandon, and contains about 675 acres. A part of the land lies in the valley of the Assiniboine River, and part of it consists of bluffs and higher table land above the bluffs. The valley land, which varies from 20 to 30 feet above the usual level of the river, has a rich dark clay loam soil and a subsoil of clay. Leaving the river the slope upward is continued, the soil gradually changing to a dark sandy loam averaging from 12 to 15 inches deep with a subsoil varying from sandy to clay. The whole area of land from the river to the foot of the bluffs which form the boundary of the valley, is over 500 acres. The bluffs vary in their inclination, some rise with a gradual slope to the top while others are more precipitous, the spaces between them being broken up into ravines of varying width in which grow a consi-

derable variety of shrubs and plants and some trees, chiefly poplar and scrub oak. The soil on these slopes is a sandy loam, much of it of good quality and from 9 to 15 inches deep resting on a gravelly or gravelly clay subsoil.

Some of the higher land above the bluffs—of which there is in all about 100 acres—is of poorer quality, mixed with more or less gravel, other parts, however, of this land are covered with a dark, sandy loam of good quality. This farm has many advantages. It has a large area of soil which fairly represents the great grain-growing areas in Manitoba, it has also that variety of soils which makes it very suitable for the carrying on of experimental work, and has also the advantage of an abundant supply of spring water. It lies in the centre of one of the large grain-growing districts and is easily accessible to all the more settled portions of the province by rail. The situation of the farm is commanding and it can be seen from the city; a good view of it is also obtained from the main line of the Canadian Pacific Railway for several miles west of Brandon.

WORK DONE AND IN PROGRESS.

Possession of this farm was had in the early part of July, 1888. Mr. S. A. Bedford, who had resided many years in Manitoba and the North-west Territories and had been a successful farmer, was appointed Superintendent and has conducted the work ever since to the great satisfaction of the farmers of the province.

Here much attention is given to methods of treatment of land for crop, different methods of sowing and the sowing at different depths, to find out which gives the best results. Many varieties of cereals have been tested to ascertain which are best adapted to the climate and the trial plots of a large number of varieties of the more important farm crops have been conducted here for some years past, as at the other farms, to gain information as to their relative productiveness and earliness.

Experiments have also been made with remedies for the prevention of smut in grain with much success, also in the growing of flax, millets and Indian corn for ensilage. The value of many native and imported grasses for hay and pasture has been tested and satisfactory conclusions reached. Other fodder plants and fodder mixtures have also been tried, including the growing of mixed cereals and cutting and curing them while green as hay, and it has been shown that by this method any farmer can provide at very little cost or labour, a large quantity of excellent fodder material on his own farm.

Bulls of the most serviceable breeds are kept for the improvement of stock. Experiments have also been made in the feeding of milch cows and steers to learn the best and cheapest methods of producing milk and beef from the fodders most generally available to the farmers of Manitoba.

TESTING OF FRUIT AND FOREST TREES, AND SHRUBS.

Since this farm was established a large number of the hardiest varieties of fruits obtainable have been tested there, and while many sorts of small fruits have succeeded well, very little success has yet attended the efforts made to grow the larger fruits. Experiments are, however, still in progress along this line. Much success has followed the planting of forest trees for shelter and large wind breaks have been established. The main roads have been planted with avenues, and many different sorts of rapid growing trees have been used to form hedge-like inclosures which furnish excellent protection for small fruits and such other crops as are apt to be injured when planted in exposed positions. Much attention has also been given to the growing of ornamental trees and shrubs of which more than 200 varieties of those tested have been found hardy in this climate. The work in all its branches has been most helpful to the farmers residing in that province.

EXPERIMENTAL FARM FOR THE NORTH-WEST TERRITORIES.

Since by far the larger part of the land open for settlement on the North-west plains consists of open prairie, when selecting the site for an Experimental Farm for this part of the Dominion, it was thought best that a piece of bare and open prairie land should be chosen for this purpose. The land selected was a section adjoining the town of Indian Head, in Eastern Assiniboia. Indian Head is on the main line of the Canadian Pacific Railway, 44 miles east of Regina, the capital, 104 miles west of the Manitoba boundary, 105 miles north of the boundary line between the United States and Canada, and 1,618 miles distant from the Central Experimental Farm at Ottawa. The farm chosen consists of 680 acres and lies on the north side of the railway which it skirts for about a mile. The soil is of excellent quality. The north half of the section is covered with a black friable clay loam, mixed with a little sand and varying in depth from one to three feet with a yellowish brown clay subsoil. The soil on the larger part of the south half is a heavy clay loam with portions (amounting in all to about 100 acres) of sandy loam. Through this section, running in a winding and irregular manner are two coulées or ravines, in one of which a small creek flows during the early spring months, which is fed by a chain of small lakes six miles distant. This creek dries up during the summer, but by erecting two dams across this ravine a small lake has been formed, where a good supply of water is retained, ample for the requirements of stock and for general farm purposes throughout the season.

The relatively short distance, 182 miles, between this farm and the site chosen for the Experimental Farm for Manitoba naturally raises the question as to the necessity for two experimental farms so near each other. The Brandon site fairly meets the requirements of the province of Manitoba, also the country for a few miles beyond the boundary line, but west of this changes begin to take place in the climate, which become more marked after travelling forty or fifty miles. From thence westward as far as general settlement has been made, the rainfall is usually less than in Manitoba, and occasional hot winds prevail during the summer season. Strong winds also during the spring season are more prevalent. These and other climatic peculiarities compel the farmers in the Territories to vary their methods in treating the soil to prepare for crop. Much of the soil also is different in its texture and character, and this feature is fairly represented by the land at Indian Head. Further, the Indian Head farm was an open prairie without tree or shrub, while the Brandon site was partly a valley farm with sheltered ravines in the bluffs, clothed with shrubs and small trees.

THE GROWING OF FOREST TREES ON THE NORTH-WEST PLAINS.

The question of the growing of forest trees for shelter is of great importance to the settler on the open plains in the North-west, and while experiments carried on at Brandon would be of value to most of the farmers in Manitoba, they would not always be a safe guide to those in the North-west Territories. The differences in climate, soil and situation between these two sites were thought sufficient to justify the establishment of the two farms, and the experimental operations in agriculture, horticulture and forestry which have been carried on since these farms were established has given a vast amount of useful and practical information most helpful to the farmers in the North-west Territories which has enabled them the better to meet the varying conditions to which they are individually subjected.

SITUATION AND SOIL.

The situation at Indian Head is central for the farmers located in the North-west. It is in the midst of a large and thriving settlement extending to the Qu'Appelle River, and beyond this north for about 25 miles through the Pheasant Plains. The country is also settled south of the railway for about 10 miles and the farm is accessible from all points in the Territories either by railway or trails. The soil is of that varied character which

makes it specially useful for experimental purposes, part of it is representative of the clay and sandy loams to the east, also of the areas which lie to the north and north-west, while the heavy clay loam on the south half of the section, although somewhat different in colour and texture, sufficiently represents the large belts of clay lands to the west and south-west.

Possession of the Indian Head farm was had early in the spring of 1888, when work was at once begun. Mr. Angus Mackay, who was one of the early settlers in that country and a successful farmer, was chosen as Superintendent and under his judicious and careful management excellent progress has been made. The farm was fenced the first season, and land prepared for crop in 1889. To meet the need for shelter on this open prairie land, tree planting on a fairly large scale was begun as soon as practicable, and although at first progress was rather slow, the trees first planted soon formed more or less protection for those put in subsequently, and now all are doing well. A shelter belt 100 feet wide, made by planting the trees 5 feet apart each way, has been located along the west and north boundaries for 1¾ miles. A large number of trees have also been planted in blocks varying from half an acre to five acres in extent, also in avenues and in hedges and hedge inclosures, and there are now growing on this farm more than 100,000 trees.

EXPERIMENTS AND THEIR RESULTS.

The results of the experiments carried on in the treatment of land to prepare it for crop have demonstrated the importance of the summer-fallowing of land in this part of the Dominion, which consists of early summer ploughing and several subsequent harrowings to destroy weeds. This treatment conserves the moisture in the land and puts it in the best condition for early sowing the following spring. Different methods of sowing have been practised, also the sowing at different depths and with different quantities of seed per acre, and much practical information has been gained of great value to the settlers. Preventives of smut in grain have also been tried here with much success. Many tests are also made each year with a large number of different sorts of cereals, fodder crops and roots to find out those which are the most profitable to grow in this climate. The growing of grasses, mixed grain crops and spring rye to be cut green and cured as hay has been carried on with much advantage. In this relatively drier climate the value of good grass for hay and pasture can scarcely be over-estimated, and among the most important of all the results gained by tests on this farm are those which have established the value of the Awnless Brome grass, *Bromus inermis*, in the North-west. This grass is very hardy, is a strong grower, endures drought well, makes a very early growth in the spring and yields fine crops of excellent hay very nourishing for cattle. Large quantities of the seed of this useful grass have been ripened at Indian Head and Brandon, and several thousand sample bags of about 1 lb. each have been sent free to farmers in different parts of the North-west Territories and Manitoba for trial, and the reports received regarding the general usefulness of this grass are most satisfactory.

Experiments have also been conducted in the feeding of stock, the fattening of swine and the management of poultry. Male animals are also kept at this farm which have been very serviceable in improving the character of the stock in that part of the Territories. Many varieties of small fruits have been successfully grown at Indian Head, but of the larger fruits tried none have yet succeeded; experiments with these fruits are however still going on. Many species and varieties of economic and ornamental trees and shrubs have been tested here, and of those tried about 150 species and varieties have proved hardy.

EXPERIMENTAL FARM FOR BRITISH COLUMBIA.

The most westerly and the last chosen of all the Experimental Farms was that selected as a site for the conducting of experiments likely to prove useful to the farmers of British Columbia. This was located at Agassiz in the coast climate of that province, about 70 miles east of Vancouver and 62 miles from New Westminster, near which place lie the fertile delta lands of the Fraser estimated at from 75,000 to 100,000 acres. Port Haney is distant 44 miles, where by crossing the river the agricultural municipality of Langley is reached. It is 28 miles to Mission, the terminus of the railway to Washington and California, and from this point river steamers run up the Fraser to the farming districts of Sumas and Chilliwack. Eastward the distance to Hope is 18 miles, to Yale 32 miles and to Lytton 86 miles, and near this latter place the drier central area of land in British Columbia begins. The distance from Ottawa to Agassiz is 2,715 miles.

In selecting a site for this farm it was thought desirable that the land should be of fairly good quality, combining an area of meadow land suitable for stock and the growing of grain, with higher meadow and bench lands, adapted for fruit growing. That the land should be high enough above the banks of adjacent rivers to prevent its being overflowed during the highest floods, also that it should be accessible by rail and water. It was further desired that the location should be central, and the capabilities of the farm fairly representative of the greater part of the farming lands in the coast climate of this province.

SITUATION, CONDITION AND SOIL.

The land chosen at Agassiz was found to have most of the advantages desired. The part purchased consisted of about 300 acres of valley land opposite the railway station at Agassiz, and extending eastward, its southern boundary fronts on the line of railway for nearly half a mile. The eastern boundary lies along the road leading to the Harrison Hot Springs, which are about 5 miles distant. About 35 acres of this land had for a time been under partial cultivation but was now partly covered with scrub. On about 200 acres of the land the larger trees had been cut and removed; the stumps however were left in the ground and about them had sprung up a strong growth of young trees and scrub. Nearly 50 acres were covered with fine timber, chiefly Douglas spruce, *Pseudotsuga Douglasi*, with some cedar, *Thuya gigantea*. There were also a few acres of higher bench lands at the rear of the farm partly wooded, which would be very suitable for fruit growing. The farm is protected on the north by a series of rocky heights ranging from 900 to 1,200 feet in altitude, on which there are many patches of bench land, some of them covering a considerable area. On the summit of this ridge there is also a large piece of comparatively level land with a good soil, of which use can no doubt eventually be made. Eight hundred acres of this broken mountain land, which was still in the hands of the Government, was added to the valley land composing the farm, making 1,100 acres in all.

The soil of the land in the valley varies from a good sandy loam, with occasional patches of gravel, and sandy loam mixed with clay, to a loam almost wholly clay; from 9 to 12 inches in depth. The subsoil is porous, sandy in some places, in others a sandy clay resting on gravel which is everywhere found from 4 to 8 feet below the surface and affords good natural drainage. All of this land is sufficiently elevated to prevent its being overflowed by the Fraser River even in the highest floods.

Possession of this farm was not had until September, 1889, when on the 19th of that month, work was begun under the superintendence of Mr. Thos. A. Sharpe, a farmer with much experience, who has shown himself to be an energetic, capable and efficient officer. During the nine years which have passed since the work on this farm was begun, much progress has been made. A large area of land has been cleared and nearly 150 acres in all, brought under cultivation.

PLANTING OF LARGE TRIAL ORCHARDS.

The climate here is very suitable for the growing of fruit, and as the fruit industry is assuming large proportions and promises to become one of great importance to this province, to aid the fruit growers in the work of selecting the best and most profitable sorts for planting large trial orchards have been established on the Experimental Farm, for the purpose of testing side by side with Canadian sorts, the fruits of all other countries with similar climates, so that reliable information as to the most promising and useful varieties for this climate, may be available to guide the planter in his selection.

Already about 2,500 different sorts have been brought together and are being tested, not only in the orchards which have been established in the valley lands, but also on the bench lands on the mountain side, where four orchards have been planted at different heights from 150 to 1,100 feet, containing in all about 900 trees.

On the sides of the rocky heights forming the background of the farm as well as on the level land, there have also been planted a large number of forest trees, especially those representing the more valuable hardwoods of the east, such as black walnut, butternut, hickory, elm, ash and oak, and many of these are making good growth. The forests of British Columbia are deficient in hardwood timber trees and if these can be grown to advantage in that climate on rocky hill-sides, such as are of no value for agricultural purposes, this branch of tree culture may become a profitable industry. Many different sorts of ornamental trees and shrubs are also under trial.

OTHER LINES OF WORK CARRIED ON.

As at the other branch farms, many useful lines of work have been carried on in the cultivation and testing of different sorts of grain, fodder plants and roots to find out those best adapted to the climate of this country. Trial plots have also been established for several years to gain information as to the best time for the sowing of different sorts of farm crops. Many experiments have also been tried with different breeds of cattle, swine and poultry. A large number of varieties of vegetables and flowers are also tested every year, and thus the work is made helpful and interesting to all classes of the community.

GENERAL WORK OF THE EXPERIMENTAL FARMS.

Among the different lines of work which have been carried on at all the Experimental Farms, but more largely at the Central Farm may be mentioned the distribution of samples of grain for the improvement of seed. These are sent out by mail free on application, in sample bags weighing three pounds, one sample only being sent to each farmer. More than 100,000 farmers have received such samples during the past ten years. More than 12,000 packages of seedling trees, shrubs and plants, and more than six tons of the seeds of hardy trees suitable for the North-west have been sent out in like manner, also several tons of the seed of the Awnless Brome grass, *Bromus inermis*. The tree seeds, and the Brome grass have been distributed in sample bags of one pound each. An annual report is published containing particulars of the work done at each farm, and this report is sent from the Central Farm to every farmer in the Dominion who asks for it. More than 50,000 copies are now distributed each year. Occasional bulletins on special subjects are also issued from time to time which reach a large proportion of the most intelligent farmers in the country. The officers at all the Experimental Farms attend every year, many of the more important meetings of farmers held in different parts of Canada, where opportunities are afforded of giving further explanations regarding the work conducted and the results achieved from year to year.

EXPERIMENTAL WORK

CONDUCTED AT THE CENTRAL EXPERIMENTAL FARM, OTTAWA ONTARIO.

EXPERIMENTS WITH OATS.

Sixty-nine varieties of oats have been tested in the uniform trial plots during the season of 1898 in order to gain information regarding their relative yield, earliness of ripening and other characteristics. They were all sown from the 14th to 16th of April on plots of $\frac{1}{40}$th acre each. The previous crop was wheat. The soil was a sandy loam of good quality which received a dressing of barn-yard manure, about 12 tons per acre, during the winter of 1895-96, the manure being placed fresh on the frozen ground in small piles of about half a cart load each and spread in the spring. The land was gang-ploughed shallow in 1897 shortly after harvest to start shed grain and weed seeds and ploughed again later in the autumn about 8 inches deep, disc-harrowed twice in the spring of 1898 and harrowed twice with the smoothing harrow before sowing. The seed was sown at the rate of two bushels per acre and the land was rolled after sowing before the grain came up.

FIELD CROPS OF OATS.

Fifteen varieties of oats have been further tested in field crops, covering 62¼ acres in all. The area occupied by each variety and the crops obtained from each sort are given below in the order of their yield. The soil of these fields varied much in quality,

which has materially affected the crops. The Abundance, Wallis, and Siberian which are among the best yielding varieties here stand low in the list on account of the poor quality of the soil on which they were grown.

American Beauty.—5 acres. The soil was a sandy loam of fair quality, a part of it peaty. The previous crop was hay. The land received an application during the winter of about 10 tons of barn-yard manure per acre which was distributed fresh from the barn-yard on the frozen ground in small piles of about one-third of a cart load each, and spread in the spring. It was then ploughed under with the sod about six inches deep and harrowed with the smoothing harrow before sowing. Sown 20th April; 2 bushels per acre; came up 2nd May, and was ripe 29th July. The time to mature was 100 days. Yield per acre, 82 bushels 11 pounds; weight per bushel, 36½ pounds. Length of head, 9 to 10 inches, branching; length of straw, 40 to 48 inches. Made a strong even growth; all standing well. There was no smut, but the leaves were slightly rusted.

Banner.—4 acres. The soil was a heavy sandy loam of good quality, more or less mixed with clay. The previous crop was roots. The land was manured in the spring of 1893 with about 18 tons of barn-yard manure per acre. No fertilizer has been applied since. It was ploughed in the spring of 1898 about 6 inches deep, and harrowed twice with the smoothing harrow before sowing. Sown 18th April; 2 bushels per acre; came up 30th April, and was ripe 27th July. The time to mature was 100 days. Yield per acre, 77 bushels 31 pounds; weight per bushel, 35 pounds. Length of head, 8 to 10 inches, branching; length of straw, 42 to 48 inches. Growth strong and even; all standing well. There was no smut, and the leaves were very slightly rusted.

Mennonite.—3 acres. Soil a light sandy loam of rather poor quality. This land was manured in 1894 with about 18 tons of barn-yard manure per acre. No fertilizer has been applied since. The previous crop was hay. The land was ploughed in the autumn of 1897 about 8 inches deep and cultivated once the following spring, and harrowed once with the smoothing harrow before sowing. Sown 15th April; 1¾ bushels per acre; came up 28th April, and was ripe 25th July. The time to mature was 101 days. Yield per acre, 64 bushels 33 pounds; weight per bushel, 34 pounds. Length of head, 7 to 9 inches branching; length of straw, 40 to 46 inches. Growth strong and even; all standing well. There was no smut, and the leaves were very slightly rusted.

Joanette.—1¼ acres. The soil was part peaty, and part sandy loam. The land was manured in the spring of 1897 with about 12 tons of barn-yard manure per acre. It was ploughed late in the autumn of 1897 about 8 inches deep, and in the following spring it was disc-harrowed once and harrowed twice with the smoothing harrow before sowing. The previous crop was oats cut green for feeding. Sown 21st April; 1½ bushels per acre; came up 3rd May, and was ripe 1st August. The time to mature was 102 days. Yield per acre, 63 bushels 18 pounds; weight per bushel, 37 pounds. Length of head, 7 to 9 inches, branching; length of straw, 34 to 38 inches. Growth medium and even; all standing well. There was no smut, but the leaves were slightly rusted.

Improved Ligowo.—1½ acres. Soil a sandy loam of fair quality which received a dressing of barn-yard manure in the spring of 1896 of about 12 tons per acre. No fertilizer has been applied since. The previous crop was wheat. The land was ploughed in the autumn of 1897 about 8 inches deep, and in the following spring disc-harrowed twice and harrowed twice with the smoothing harrow before sowing. Sown 27th April; 1¾ bushels per acre; came up 7th May, and was ripe 29th July. The time to mature was 93 days. Yield per acre, 62 bushels 27 pounds; weight per bushel 38¼ pounds. Length of head, 7 to 9 inches, branching; length of straw, 38 to 44 inches. Made a strong and even growth; all standing well. There was no smut, but the leaves were very slightly rusted.

Improved Ligowo.—6½ acres. Soil a light sandy loam of good quality. This land was manured in the autumn of 1897 with about 10 tons of barn-yard manure per acre. The previous crop was partly corn and part potatoes. It was ploughed in the autumn of 1897 about 6 inches deep, and the following spring it was disc-harrowed once, and harrowed twice with the smoothing harrow before sowing. Sown 12th April; 1¾ bushels per acre; came up 26th April, and was ripe 25th July. The time to mature was 104 days. The yield per acre was 62 bushels 10 lbs.; weight per bushel, 38¼ pounds. Length of head, 7 to 9 inches, branching; length of straw, 42 to 46 inches. Made a strong and even growth; all standing well. There was no smut, and the leaves were very slightly rusted.

Golden Beauty.—5 acres. Soil a sandy loam of fair quality, a part of it peaty. The previous crop was hay. The land received an application of barn-yard manure of about 10 tons per acre, distributed fresh from the barn yard in small piles of about one-third of a cart load each, during the winter of 1897-98, which was spread in the spring, and ploughed under with the sod about 6 inches deep, and harrowed twice with the smoothing harrow before sowing. Sown 20th April; 2 bushels per acre; came up 2nd May, and was ripe 20th July. The time to mature was 100 days. Yield per acre, 62 bushels 31 pounds; weight per bushel, 36 pounds. Length of head, 9 to 10 inches, branching; length of straw, 42 to 48 inches, made a strong and even growth; all standing well. There was no smut, but the leaves were slightly rusted.

White Schonen.—3¾ acres. Soil a sandy loam of fair quality, which was manured in the spring of 1898, with about 12 tons of barn-yard manure per acre. The previous crop was hay. The manure was ploughed under soon after spreading about 6 inches deep, and the land was harrowed twice with the smoothing harrow before sowing. Sown 30th April; 1¾ bushels per acre; came up 8th May, and was ripe 5th August. The time to mature was 98 days. Yield per acre, 57 bushels 26 pounds; weight per bushel, 36 pounds. Length of head, 8 to 9 inches, branching; length of straw, 38 to 43 inches. Made a strong and even growth; all standing well. There was no smut, but the leaves were very slightly rusted.

Wallis.—4 acres. Soil a sandy loam, rather light but of fair quality, which received a coating of barn-yard manure of about 12 tons per acre in the spring of 1895. No manure or other fertilizer has been applied since, except a good crop of green clover, which was sown

with the previous crop and ploughed under in the autumn of 1897. The previous crop was barley. The ploughing in the autumn was about 8 inches deep, and in the spring of 1898 the land was disc-harrowed once and harrowed twice with the smoothing harrow before sowing. Sown 19th April, 2 bushels per acre; came up 30th April, and was ripe 28th July. The time to mature was 100 days, and the yield per acre was 57 bushels 2 pounds; weight per bushel, 36¼ pounds. Length of head, 9 to 10 inches, branching; length of straw, 42 to 48 inches. Growth strong and even, and all standing well. There was no smut, but the leaves were very slightly rusted.

Siberian O.A.C.—3½ acres. Soil a sandy loam, rather light but of fair quality, which received a coating of barn-yard manure of about 12 tons per acre in the spring of 1895. No manure or other fertilizer has been applied since, except a good crop of clover. Clover seed in the proportion of 10 lbs. per acre, was sown with the previous crop of barley and ploughed under in the autumn of 1897. The autumn ploughing was about 8 inches deep. In the spring it was disc-harrowed once, and harrowed twice with the smoothing harrow before sowing. Sown 19th April; 1¾ bushels per acre; came up 30th April, and was ripe 29th July. The time to mature was 101 days. Yield per acre; 57 bushels; weight per bushel, 37 pounds. Length of head, 9 to 10 inches, branching; length of straw, 42 to 48 inches. Made a strong even growth; a few spots lodged. There was no smut, but the leaves were very slightly rusted.

Siberian O.A.C.—1½ acres. This also was adjoining the 3½ acres, and the character of the land was the same. It received a similar application of manure in 1895, and also a dressing of barn-yard manure of about 12 tons per acre in the spring of 1897. In the spring of 1898 it received an application of unleached wood ashes, of about 100 bushels per acre. The previous crop was sunflowers. The land was ploughed in the autumn of 1897 about 8 inches deep, and in the following spring it was disc-harrowed once, and harrowed twice with the smoothing harrow before sowing. Sown 19th April; 1¾ bushels per acre; came up 30th April, and was ripe 29th July. The time to mature was 101 days. The yield per acre was 38 bushels 32 pounds; weight per bushel, 37 pounds; length of head, 8 to 9 inches, branching; length of straw, 38 to 42 inches. Made a medium and even growth; all standing well. There was no smut, but the leaves were very slightly rusted.

Bavarian.—2½ acres. Soil a sandy loam, rather light but of fair quality, which received a dressing of barn-yard manure of about 12 tons per acre in the spring of 1895. No manure or other fertilizer has been applied since, excepting a good crop of green clover which was sown with the previous crop of barley in the spring of 1897, 10 lbs. of Mammoth Red clover seed being used per acre. This produced a thick mat of green growth which was ploughed under in the autumn about 8 inches deep. In the spring of 1898 the land was disc-harrowed once, and harrowed twice with the smoothing harrow before sowing. Sown 20th April; 2 bushels per acre; came up 30th April, and was ripe 28th July. The time to mature was 99 days. The yield per acre was 56 bushels 12 pounds; weight per bushel, 36 pounds. Length of head, 9 to 10 inches; length of straw, 42 to 48 inches. Growth strong and even; all standing well. There was no smut, but the leaves were very slightly rusted.

Abundance.—4¾ acres. The soil was part peaty and part sandy loam. The land was manured in the spring of 1897 with about 12 tons of barn-yard manure per acre. It was ploughed late in the autumn of 1897 about 8 inches deep, and in the following spring it was disc-harrowed once and harrowed twice with the smoothing harrow before sowing. Sown 22nd April; 1¾ bushels per acre; came up 3rd May; and was ripe 28th July. The time to mature was 97 days. Yield per acre, 55 bushels 18 pounds; weight per bushel, 36¼ pounds. Length of head, 7 to 9 inches, branching; length of straw, 38 to 44 inches. Growth medium and even; all standing well. There was no smut, but the leaves were very slightly rusted.

Golden Giant.—10 acres. Soil a light sandy loam of rather poor quality. The land was manured in 1895 with about 12 tons of barn-yard manure per acre. The previous crop was oats. It was ploughed very shallow Sept. 1st, 1897, and subsequently cultivated at short intervals as the land was rather weedy, so as to keep down all growth until late in the autumn. In the following spring it was cultivated twice with a large cultivator which stirred the soil nearly six inches deep, and harrowed twice with the smoothing harrow before sowing. Sown 14th April; $1\frac{3}{4}$ bushels per acre; came up 28th April, and was ripe 2nd August. The time to mature was 110 days. The yield per acre was 54 bushels 21 pounds; weight per bushel $35\frac{1}{2}$ pounds. Length of head, 9 to 10 inches; sided; length of straw, 42 to 48 inches. Made a strong and even growth; all standing well. There was no smut, and the leaves were very slightly rusted.

Columbus.—3 acres. This variety was sown adjoining the Golden Giant, and the quality of the soil and the preparation and treatment of the land was the same. Sown 14th April; $1\frac{3}{4}$ bushels per acre; came up 28th April, and was ripe 25th July. The time to mature was 102 days. Yield per acre, 51 bushels 19 pounds; weight per bushel, 34 pounds. Length of head, 8 to 9 inches, branching; length of straw, 38 to 42 inches. Made a medium growth; all standing well. There was no smut, and the leaves were very slightly rusted.

Early Gothland.—5 acres. The soil was a sandy loam of fair quality which received a dressing of barn-yard manure in the spring of 1896 of about 12 tons per acre. No fertilizer has been applied since. The previous crop was wheat. The land was ploughed in the autumn of 1897 about 8 inches deep, and disc-harrowed twice in the following spring and harrowed twice with the smoothing harrow before sowing. Sown 27th April; $1\frac{3}{4}$ bushels per acre; came up 7th May, and was ripe 29th July. The time to mature was 93 days. Yield per acre, 47 bushels 27 pounds; weight per bushel, 39 pounds. Length of head, 8 to 10 inches; half sided. Length of straw, 38 to 46 inches. Made a strong and even growth; all standing well. There was no smut, but the leaves were very slightly rusted.

EXPERIMENTS WITH BARLEY.

During 1898 experiments have been conducted with fifty varieties of barley, of which twenty-two were two-rowed sorts, and twenty-eight six-rowed. These were all sown in plots of $\frac{1}{40}$th acre each. The previous crop was wheat. The land selected for the barley plots was adjoining that used for the test of varieties of oats. The soil was similar and the preparation and treatment of the land the same. These plots were all sown from the 16th to the 18th of April, at the rate of 2 bushels per acre for the two-rowed sorts and $1\frac{3}{4}$ bushels per acre for the six-rowed.

Field Crop of Two-rowed Barley.

Canadian Thorpe.—$4\frac{1}{2}$ acres. Soil a sandy loam of fair quality. The land was manured in 1895 with about 12 tons of barn-yard manure per acre. No fertilizer has been applied since. The previous crop was oats. The land was ploughed late in the autumn of 1897 about 8 inches deep, and disc-harrowed the following spring and harrowed twice with the smoothing harrow before sowing. Sown 14th April ; 2 bushels per acre ; came up 26th April, and was ripe 23rd July. The time to mature was 100 days. Yield per acre, 32 bushels 6 pounds ; weight per bushel, $51\frac{1}{2}$ pounds. Length of head, 3 to $3\frac{1}{2}$ inches ; length of straw, 38 to 44 inches ; growth medium ; all standing well. There was no smut or rust.

FIELD CROPS OF SIX-ROWED BARLEY.

Royal.—7¼ acres. Soil a sandy loam of fair quality, with patches of heavier soil which were partly clay. This land received a dressing of about 15 tons of barn-yard manure per acre in the spring of 1897. No fertilizer has been applied since. The previous crop was corn. The land was ploughed late in the autumn about 8 inches deep and disc-harrowed twice the following spring, and harrowed twice with the smoothing harrow before sowing. Sown 15th April ; 1¾ bushels per acre ; came up 27th April, and was ripe 13th July. The time to mature was 89 days. Yield per acre, 40 bushels 6 pounds ; weight per bushel, 51 pounds. Length of head, 2½ to 3½ inches ; length of straw, 36 to 42 inches. Growth medium and even ; all standing well. There was some smut, but no rust.

Mensury.—4 acres. Soil partly clay loam, partly sandy loam and part peaty. This land was manured in the spring of 1896, with about 12 tons of barn-yard manure per acre. In the spring of 1898 a thick mat of clover was ploughed under. The previous crop was oats, with which the clover was sown at the rate of 10 pounds of seed per acre. In the spring of 1898 it was ploughed about six inches deep, then disc-harrowed and harrowed twice with the smoothing harrow before sowing. Sown 23rd April ; 1¾ bushels per acre ; came up 3rd May, and was ripe 20th July. The time to mature was 88 days. Yield per acre, 46 bushels 41 pounds ; weight per bushel, 45½ pounds. Length of head, 3 to 3½ inches ; length of straw, 38 to 42 inches. Growth strong and even ; all standing well. There was no smut or rust.

Oderbruch.—4 acres. This and the three following plots were adjoining that of Mensury, the soil was similar and the preparation and treatment of the land the same. Sown 23rd April; $1\frac{3}{4}$ bushels per acre; came up 10th May and was ripe 20th July. The time to mature was 88 days. Yield per acre, 44 bushels 30 pounds; weight per bushel, 49 pounds. Length of head, 3 to $3\frac{1}{4}$ inches; length of straw, 36 to 40 inches. Growth medium to strong; standing fairly well. There was no smut and no rust.

Success.—2 acres. Sown 23rd April; $1\frac{3}{4}$ bushels per acre; came up 4th May, and was ripe 16th July. The time to mature was 84 days. Yield per acre, 39 bushels 13 pounds; weight per bushel, 45 pounds. Length of head, $2\frac{1}{2}$ to 3 inches; beardless; length of straw, 36 to 40 inches. Growth medium and even, standing fairly well. There was no smut or rust.

Champion.—2 acres. Sown 23rd April, $1\frac{3}{4}$ bushels per acre; came up 4th May, and was ripe 18th July. The time to mature was 86 days. Yield per acre, 41 bushels 18 pounds; weight per bushel 43 pounds. Length of head, $3\frac{1}{2}$ to $3\frac{3}{4}$ inches; beardless; length of straw, 38 to 44 inches. Growth medium and even; all standing well. There was no smut or rust.

Trooper.—2 acres. Sown 23rd April; $1\frac{3}{4}$ bushels per acre; came up 4th May; and was ripe 22nd July. The time to mature was 90 days. Yield per acre, 40 bushels 13 pounds; weight per bushel, 49 pounds. Length of head, $2\frac{1}{2}$ to $2\frac{3}{4}$ inches; length of straw, 32 to 36 inches. Growth medium and even; all standing well. There was some smut but no rust.

EXPERIMENTS WITH FALL WHEAT.

Twenty-four varieties of fall wheat have been under trial during the past season, most of them in plots of $\frac{1}{40}$th of an acre each. They were all sown on the 7th of September, 1897, and harvested from the 14th to the 26th of July, 1898. The soil was a sandy loam of medium quality which received a dressing of barn-yard manure of about 12 tons to the acre during the winter of 1895-96. This was placed on the frozen land fresh from the barn-yard in small heaps of about half a cart load each and spread and ploughed under in the spring. No manure or other fertilizer has been applied since. The previous crop was pease. The land was gang-ploughed shallow shortly after harvest in 1897 to start shed grain and weed seeds, and ploughed again in September about 8 inches deep and harrowed with the smoothing harrow before sowing. The growth of all the plots was strong and even but three or four of the varieties which gave the smallest crops were more or less winter killed. Most of the grain harvested was unusually fine and plump.

Stanley. Preston.

Cross-bred wheats, produced at the Central Experimental Farm, Ottawa, Ontario. [25]

EXPERIMENTS WITH SPRING WHEAT.

Experiments have been conducted during the past season with sixty-five varieties of spring wheat, all grown in plots of $\frac{1}{40}$th of an acre each. The soil was a sandy loam of medium quality, which received a dressing of barn-yard manure of about 12 tons to the acre during the winter of 1895-96. This was placed on the frozen land fresh from the barn-yard, in small heaps of about half a cart load each and spread and ploughed under in the spring. No manure or other fertilizer has been applied since. The previous crop was pease. The land was gang-ploughed shallow shortly after harvest in 1897 to start shed grain and weed seeds, and ploughed again late in the autumn about 8 inches deep. In the spring of 1898 it was disc-harrowed twice, and harrowed with the smoothing harrow twice before sowing. The seed was sown from the 20th to the 22nd of April at the rate of 1½ bushels per acre and the land was rolled before the grain came up.

In the foregoing list there are included forty-one of the new cross-bred sorts, which have been originated at the experimental farms. A list of the names and parentage of fifteen cross-bred sorts was given in the Annual Report for 1896, page twenty, and a second list of sixteen more in the Annual Report for 1897, page sixteen. This year thirty of the thirty-one contained in these two lists have been tried again and the following eleven new sorts added to the list:—

32.	Campbell—Gehun..........	Female with	Campbell's White Chaff	Male.
33.	Weldon—Red Fife..........	"	Hard Red Calcutta...	"
34.	Clyde—Hard Red Calcutta...	"	Red Fife............	"
35.	Byron—Campbell's White Chaft	"	Gehun..............	"
36.	Benton—Gehun	"	Campbell's White Chaft	"
37.	Cassel—Hard Red Calcutta...	"	Red Fife..........	"
38.	Early Riga—Gehun..........	"	Onega.............	"
39.	Norval—Delhi..............	"	Manchester, Fall Wheat	"
40.	Hastings—Colorado..........	"	Gehun..............	"
41.	Chester—Alpha.............	"	Gehun..............	"
42.	Allan—Colorado...........	"	Gehun..............	"

Of these results in cross fertilizing one was originated at the Central Experimental Farm by the Director, in 1891, No. 42. Six were the results of the work of Mr. W. T. Macoun, also at the Central Farm, one was produced in 1890, No. 39, and five were produced in 1891, Nos. 32, 35, 36, 38 and 40. Four were originated by Dr. A. P. Saunders in 1892, one, No. 33, at the branch experimental farm at Brandon, Manitoba, two at the branch farm at Indian Head, N.W.T., Nos. 34 and 37, and one at the branch farm at Agassiz, No 41.

Field Crops of Spring Wheat.

Preston.—2 acres. The soil in this plot was a heavy sandy loam of good quality, more or less mixed with clay. The previous crop was roots. The land was manured in the spring of 1893 with about 18 tons of barn-yard manure per acre; no fertilizer has been applied since. The land was ploughed in the spring of 1898, about 6 inches deep, and harrowed twice with the smoothing harrow before sowing. Sown 18th April; 1½ bushels per acre; came up 30th April, and was ripe 26th July. The time to mature was 99 days. Yield per acre, 31 bushels 22 pounds; weight per bushel, 62 pounds. Length of head, 3½ to 3¾ inches; bearded; length of straw, 38 to 42 inches. Growth strong and even; all standing well. There was no smut, and no rust.

Stanley.—1 acre. Soil a heavy sandy loam of fairly good quality, slightly tending to clay, which received a dressing of about 15 tons of barn-yard manure per acre, in the spring of 1897. No fertilizer has been applied since. The previous crop was corn. The land was ploughed late in the autumn of 1897, about 8 inches deep and disc-harrowed twice the following spring, and harrowed twice with the smoothing harrow before sowing. Sown 16th April; 1½ bushels per acre; came up 27th April, and was ripe 26th July. The time to mature was 89 days. Yield per acre, 18 bushels 29 pounds; weight per bushel, 62½ pounds. Length of head, 2½ to 3¼ inches; beardless; length of straw, 36 to 40 inches. Growth medium and even; all standing well. There was no smut or rust.

Dion's.—1 acre. This and the next four plots referred to were all adjoining the Stanley; the soil was similar and the preparation and treatment of the land the same. Sown 16th April; 1½ bushels per acre; came up 27th April, and was ripe 26th July. The time to mature was 101 days. Yield per acre, 23 bushels 28 pounds; weight per bushel, 61¼ pounds. Length of head, 3½ to 4 inches; length of straw, 38 to 44 inches. Growth strong and even; all standing well. There was no smut and no rust.

Preston.—2 acres. Sown 16th April; 1½ bushels per acre; came up 28th April, and was ripe 26th July. The time to mature was 101 days. Yield per acre, 30 bushels 43 pounds; weight per bushel, 62 pounds. Length of head, 3½ to 3¾ inches; bearded; length of straw, 38 to 42 inches. Growth strong and even; all standing well. There was no smut, and no rust.

Wellman's Fife.—1 acre. Sown 16th April; 1½ bushels per acre; came up 27th April, and was ripe 29th July. The time to mature was 104 days. Yield per acre, 25 bushels 6 pounds; weight per bushel, 58 pounds. Length of head, 3½ to 4 inches; beardless; length of straw, 38 to 44 inches. Growth strong and even; all standing well. There was no smut, and no rust.

Monarch.—1 acre. Sown 16th April; 1½ bushels per acre; came up 27th April, and was ripe 29th July. The time to mature was 104 days. Yield per acre, 28 bushels 8 pounds; weight per bushel, 58½ pounds. Length of head, 3 to 3½ inches; beardless; length of straw, 36 to 41 inches. Growth strong and even; all standing well. There was no smut, and no rust.

Percy.—1 acre. Sown 16th April; 1½ bushels per acre; came up 28th April and was ripe 25th July. The time to mature was 100 days. Yield per acre, 25 bushels 37½ pounds; weight per bushel, 62 pounds. Length of head, 3 to 3½ inches; beardless; length of straw, 38 to 40 inches. Growth strong and even; all standing well. There was no smut, and no rust.

SPRING WHEATS FROM AUSTRALIA.

Nineteen varieties of spring wheat were received from Australia early in the year. These were all supposed to be freer from rust than other varieties and some of them were said to be rust proof. As they were received in very small quantities no satisfactory estimate could be made of the yield per acre. Probably this can be done another year. The varieties received from this source were all beardless. None of them were entirely free from rust here.

It is proposed to give these varieties further trial.

EXPERIMENTS WITH PEASE.

Sixty-six varieties of pease were included in the trial plots during the past year. The nine varieties named Harrison's Glory, Fenton, Alma, King, Kent, Canadian Beauty, Daniel O'Rourke, Trilby and Prince are not reported on for the following reason. On the 5th of August, when these were cut and drying in the field, a violent storm of wind suddenly arose which carried them all to the other end of the field and they were so mixed that it was impossible to separate them.

The pease were all sown in plots of $\frac{1}{40}$th of an acre each. The soil was a sandy loam of good quality which received a dressing of barn-yard manure about 12 tons per acre, during the winter of 1895-96. The manure was taken fresh from the barn-yard and placed on the frozen land in small piles of about half a cart load each to keep it from fermenting, and spread in the spring. The previous crop was barley. The land was gang-ploughed shallow, shortly after harvest to start shed grain and weed seeds, and ploughed later in the autumn about 8 inches deep. In the spring of 1898 it was disc-harrowed twice and harrowed twice with the smoothing harrow before sowing. From 2 to 3 bushels per acre were sown, depending on the size of the peas and all were sown from the 18th to the 20th of April.

FIELD CROPS OF PEASE.

New Potter.—One-half acre. Soil partly clay loam, and part peaty, which received a dressing of barn-yard manure of about 12 tons per acre in the spring of 1896, and has had no fertilizer since. The previous crop was oats. The land was ploughed in the spring of 1898 about 6 inches deep, turning under a good mat of clover which had been sown with the oats in 1897. The land was then disc-harrowed once and harrowed twice with the smoothing harrow before sowing. Sown 9th April; $2\frac{1}{2}$ bushels per acre; came up 9th May, and was ripe 8th August. The time to mature was 103 days. Yield per acre, 25 bushels; weight per bushel, 62 pounds. Growth medium and even; pods medium. Length of straw, 50 to 60 inches.

Canadian Beauty.—One-half acre. This and the three following plots were adjoining that of New Potter; the soil was similar and the preparation and treatment of the land the same throughout. Sown 27th April; 3 bushels per acre; came up 10th May, and was ripe 10th August. The time to mature was 105 days. Yield per acre, 29 bushels 30 pounds; weight per bushel, 64 pounds. Growth strong and even; pods large. Length of straw, 55 to 60 inches.

White Marrowfat.—One-half acre. Sown 27th April; 3 bushels per acre; came up 10th May; and was ripe 10th August. The time to mature was 105 days. Yield per acre, 28 bushels 6 pounds; weight per bushel, 63 pounds. Growth strong and even; pods large. Length of straw, 55 to 62 inches.

Creeper.—One-half acre. Sown 27th April; $2\frac{1}{2}$ bushels per acre; came up 9th May, and was ripe 8th August. The time to mature was 103 days. Yield per acre, 34 bushels 54 pounds; weight per bushel, $64\frac{1}{4}$ pounds. Growth strong and even; pods small. Length of straw, 46 to 54 inches.

Prussian Blue.—One-half acre. Sown 27th April; $2\frac{1}{2}$ bushels per acre; came up 9th May, and was ripe 6th August. The time to mature was 101 days. Yield per acre, 35 bushels 36 pounds; weight per bushel, $64\frac{1}{2}$ pounds. Growth strong and even; pods medium to small. Length of straw, 45 to 55 inches.

Common Field Peas,—5 acres. Soil sandy loam of medium quality, part of this land received in the spring of 1894 an application of about 12 tons of barn-yard manure per acre. No fertilizer has been applied since. The previous crop on part of this land was corn and potatoes, the other part had been used as a nursery for young forest trees and had not received any manure or other fertilizer. The land was ploughed in the spring of 1898, about 6 inches deep, and harrowed twice with the smoothing harrow before sowing. Sown 3rd May; $2\frac{1}{2}$ bushels per acre; came up 14th May, and was ripe 9th August. The time to mature was 99 days.

Yield per acre, 32 bushels 7 pounds. Growth medium and even; pods small. Length of straw, 40 to 52 inches.

RESULTS OF EARLY, MEDIUM AND LATE SOWINGS.

These tests were all conducted on similar land, on $\frac{1}{10}$th acre plots, the plots adjoining each other. The soil was a sandy loam of fair quality which received a dressing of barn-yard manure, about 12 tons per acre, in the autumn of 1895 when it was ploughed under. The land also received an application of unleached wood ashes in November, 1897, of about 125 bushels per acre. No fertilizers have been applied since. The previous crop was grain in experimental plots, the different kinds of grain being sown in rotation. The land was ploughed in the autumn, about 8 inches deep, and in the spring a sufficient quantity of the land for the first set of plots was gang-ploughed and harrowed twice with the smoothing harrow before sowing, the first sowing being made as soon as the land was in condition to receive the seed. The oats were sown at the rate of $2\frac{1}{4}$ bushels per acre, the Canadian Thorpe barley, 2 bushels, the Odessa $1\frac{3}{4}$, the spring wheat $1\frac{1}{2}$ bushels, the Mummy pease, $2\frac{3}{4}$ bushels and the Golden Vine, $2\frac{1}{2}$ bushels per acre. A sufficient portion of the land set aside for the subsequent sowings was worked up from week to week in the manner described, as it was needed, and in this way any weeds which had started were killed and each series of plots were given the same chance at the start as far as condition of soil was concerned.

EXPERIMENTS WITH INDIAN CORN.

During the season of 1898 twenty-six varieties of Indian corn were tested side by side on fairly uniform land. The soil was a sandy loam of fair quality, and the previous crop was hay. The land was ploughed very shallow immediately after the hay crop was taken off, and cultivated at short intervals to keep all growth down until autumn. A dressing of barn-yard manure fresh of about 12 tons per acre was distributed over this land in small piles of about one-third of a cart load each during the winter, and spread in the spring, after which it was ploughed under about six inches deep and harrowed with the smoothing harrow before planting. The varieties were all planted on the 18th of May, and were cut for ensilage on the 17th of September. The yield per acre has been calculated from the weight of the crop cut from two rows each 66 feet long.

Field Crops of Indian Corn.

The following eighteen varieties were planted in ½ acre plots, all adjoining each other on similar soil and with the same treatment. The soil was a sandy loam of fair quality, and the previous crop was hay. The land was ploughed very shallow immediately after the hay crop was taken off in 1897, and cultivated at short intervals to keep all growth down until autumn. An application of fresh barn-yard manure of about 12 tons per acre was distributed in small piles of about one-third of a cart load each to prevent it from fermenting during the winter, and spread in the spring, after which it was ploughed under about 6 inches deep and harrowed with the smoothing harrow, and marked with a wide marker before planting.

1. *Rural Thoroughbred White Flint.*—½ acre. Planted 17th May, in hills 3 feet apart each way, 4 to 5 kernels in each hill; came up 30th May, and was cut for ensilage 8th September. The growth was strong and even, leafy from top to bottom, and 8 to 9 feet high; the stalks well eared; ears in the early milk stage. Yield per acre, 17 tons 526 pounds.

2. *Mammoth Eight-rowed Flint.*—½ acre. Planted 17th May, in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 3rd September. Growth strong and even, leafy from top to bottom, 7 to 8 feet high; stalks extra well eared, and the ears well advanced in the glazed condition, some of them beginning to harden. Yield 18 tons 500 pounds per acre.

3. *Compton's Early.*—½ acre. Planted 17th May in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 3rd September. Growth strong and even; leafy from top to bottom; height, 7 to 8 feet; stalks well eared; ears well advanced in the glazed condition, some of them beginning to harden. Yield 17 tons 40 pounds per acre.

4. *King of the Earliest.*—½ acre. Planted 17th May in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 6th September. Growth strong and even; leafy on top, fairly leafy at bottom; height, 8 to 9 feet; stalks well eared: ears well advanced in the glazed condition, some of them beginning to harden. Yield 18 tons 660 pounds per acre.

5. *Extra Early Huron.*—½ acre. Planted 17th May, in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 6th September. Growth strong and even; leafy at top and fairly leafy below; height, 8 to 9 feet; stalks well eared; ears well advanced in the glazed condition, some of them beginning to harden. Yield 13 tons 1,420 pounds per acre.

6. *Cloud's Early Yellow.*—½ acre. Planted 17th May, in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 6th September. Growth strong and even; leafy at top, fewer leaves at bottom; height, 8 to 10 feet; stalks well eared; ears well advanced in the glazed condition, some of them beginning to harden. Yield 19 tons 1,820 pounds per acre.

7. *Red Cob Ensilage.*—½ acre. Planted 17th May, in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 6th September. Growth very strong and even; leafy at top with very few leaves at bottom; height, 10 to 11 feet; ears not plentiful, some beginning to form. This variety was too late in ripening to make ensilage of best quality. Yield 23 tons 160 pounds per acre.

8. *Giant Prolific Ensilage.*—½ acre. Planted 17th May, in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 6th September. Growth very strong and even; leafy above, with very few leaves below; height, 10 to 12 feet; stalks fairly well eared; ears in the early milk state. Yield 22 tons 1,840 pounds per acre.

9. *Champion White Pearl.*—½ acre. Planted 17th May, in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 6th September. Growth very strong and even; leafy above, fairly leafy below; height, 9 to 11 feet; stalks well eared; ears in late milk state. Yield 20 tons 1,490 pounds per acre.

Early Mastodon.—½ acre. Planted 17th May, in hills 3 feet apart each way; came up 29th May, and was cut for ensilage 6th September. Growth very strong and even; leafy throughout; height 10 to 12 feet; stalks well eared; ears in early milk. Yield per acre 23 tons 570 pounds per acre.

11. *Canada White Flint.*—½ acre. Planted 19th May, in hills 3 feet apart each way; came up 30th May, aad was cut for ensilage 8th September. Growth strong and even; leafy from top to bottom; height 7 to 8 feet; stalks very well eared; ears beginning to ripen. Yield 13 tons 970 pounds per acre.

12. *Pride of the North.*—½ acre. Planted 19th May, in hills 3 feet apart each way; came up 30th May, and was cut for ensilage 9th September. Growth strong and even; leafy on top, fairly leafy at bottom; height 8 to 9 feet; stalks well eared; ears beginning to ripen. Yield 16 tons 1,730 pounds per acre.

13. *Early Butler.*—½ acre. Planted 19th May, in hills 3 feet apart each way; came up 30th May and was cut for ensilage 9th September. Growth strong and even; leafy at top, fewer leaves at bottom; height 8 to 9 feet; stalks well eared; ears beginning to ripen. Yield 16 tons 1,080 pounds per acre.

14. *North Dakota.*—½ acre. Planted 19th May, in hills 3 feet apart each way; came up 30th May, and was cut for ensilage 19th September. Growth strong and even; leafy throughout; height 8 to 9 feet; stalks well eared; ears almost ripe. Yield 15 tons 770 pounds per acre.

15. *Sanford.*—½ acre. Planted 19th May, in hills 3 feet apart each way; came up 30th May and was cut for ensilage 19th September; growth strong and even; leafy throughout; height 7 to 9 feet; stalks well eared; ears in the glazed condition, some of them beginning to ripen. Yield 14 tons 440 pounds per acre.

16. *Mammoth Cuban.*—½ acre. Planted 19th May, in hills 3 feet apart each way; came up 30th May, and was cut for ensilage 19th September. Growth very strong and even; leafy above; very few leaves below; stalks well eared; ears in late milk: height, 9 to 11 feet. Yield 17 tons 790 pounds per acre.

17. *Selected Leaming.*—½ acre. Planted 19th May, in hills 3 feet apart each way; came up 30th May, and was cut for ensilage 19th September. Growth very strong and even; leafy at top; very few leaves at bottom; height, 10 to 11 feet; stalks well eared, ears beginning to ripen. Yield 19 tons 254 pounds per acre.

18. *White Cap Yellow Dent.*—½ acre. Planted 19th May, in hills 3 feet apart each way; came up 30th May, and was cut for ensilage 8th September. Growth very strong and even; leafy on top; fairly leafy at bottom; height 10 to 12 feet; stalks well eared; ears in late milk, some of them beginning to ripen. Yield 19 tons 1,010 pounds per acre.

Indian Corn Sown in Rows at Different Distances.

Three varieties of Indian corn were selected for this test. The rows most closely planted were 7 inches apart—the width of the seed-drill—and the other distances were 14, 21, 28, 35, 42 and 49 inches respectively. The object was to gain information as to weight and crop when grown under these different conditions, also the number of cobs or ears, produced both large and small. The soil was a light sandy loam of fair quality. The previous crop was hay. The land was ploughed in the summer of 1897 very shallow, immediately after the hay crop was harvested, and disc-harrowed, and subsequently cultivated at intervals to keep down all growth. During the winter this land received a dressing of about 12 tons of fresh barn-yard manure per acre which was placed on the frozen ground in small piles to prevent fermentation, of about a third of a cart load each. This was spread in the spring, ploughed under about six inches deep and harrowed with the smoothing harrow before sowing. The plots were all sown with the seed drill on 17th May, closing the spouts not required as the distance between the rows was increased, and they were cut for ensilage on the 12th of September. When harvesting the yields per acre have been estimated from rows cut from the middle of each plot.

CORN—TEST OF THREE VARIETIES WITH ROWS PLANTED AT DIFFERENT DISTANCES.

EXPERIMENTS WITH TURNIPS.

There were tested during the past season twenty varieties of turnips, all sown side by side on similar soil. The soil was a sandy loam of good quality, which was manured in the autumn of 1895 with about 12 tons of barn-yard manure per acre. The previous crop was oats. The land was ploughed early in the autumn of 1897 about 8 inches deep, and again in the spring of 1898, and harrowed twice with the smoothing harrow. The land was then made up in drills two feet apart and subsequently rolled with a heavy land roller which flattened the drills nearly one-half, leaving a firm seed bed. The seed was sown at the rate of 3 pounds per acre, and immediately after sowing there was applied on the drills, at the rate of 500 pounds per acre, a mixture composed of the following fertilizers : Odourless phosphate, 1,200 pounds ; kainite, 600 pounds ; superphosphate No. 2, 400 pounds, and nitrate of soda, 300 pounds. Four sowings were made of each variety, the first on 28rd April, second on 6th May, third on 21st May, and the fourth on the 11th of June, and all were pulled on the 13th of October. The yield per acre has been calculated from the weight of roots pulled from two rows each 66 feet long.

These turnips were sown in rows of 200 feet or more in length, which gave opportunity for further experiments after the two rows of 66 feet each, used to ascertain the yield in the first place, had been pulled. A portion of the roots in this area was left in the ground until later. to gain information as to what advantage, if any, results from

leaving turnips in the ground after the middle of October. Nineteen plots were so left until the 3rd of November, which allowed 21 days for additional growth, with the following results :—

" "	4th sowing, 2nd pulling.	26	1,226

An average gain in 21 days of 1 ton 1,813 pounds per acre.

The results of these experiments although somewhat variable, and not so striking as those of last year, point to the same conclusion—which is, that growth in turnips as a rule proceeds rapidly late in the season as long as the weather remains open.

EXPERIMENTS WITH MANGELS.

Nineteen varieties of mangels were under test during 1898. These were all sown side by side adjoining the turnips. The land was similar but rather lighter, and the treatment and preparation was the same. The drills were made up two feet apart and rolled with a heavy land roller to make a firm bed before the seed was sown. Three sowings were made, the first on the 28th of April, the second on the 6th of May, and the third on the 21st of May, and after sowing, the same mixture of fertilizers as was used on the turnips was applied on the drills of mangels in the proportion of 500 pounds per acre. The roots were all pulled on the 13th of October, and the yield per acre has been calculated from the weight of roots obtained from two rows each 66 feet long.

These results point to the importance of the early sowing of mangels.

The mangels in these tests were sown in rows 200 feet or more in length, which gave opportunity for further experiment, after the two rows of 66 feet each, used to determine the yield, had been pulled. A portion of the roots in this area was left in the ground until later, to gain information as to what advantage, if any, results from leaving mangels in the ground after the middle of October. Nineteen plots were so left until the 3rd of November, which allowed 21 days for additional growth, with the following results :—

These figures show the following results :—

	Tons.	Lbs.
Average yield per acre from 1st sowing, 1st pulling ..	26	792
" " " 2nd " ..	27	479
An average gain in 21 days of 1,684 lbs. per acre.		
Average yield per acre from 2nd sowing, 1st pulling.	21	1,162
" " " 2nd " ..	22	676
An average gain in 21 days of 1,514 lbs. per acre.		
Average yield per acre from 3rd sowing, 1st pulling.	17	216
" " " 2nd " ..	25	1,255

An average gain in 21 days of 8 tons 1,039 lbs. per acre.

It will be observed that these comparative yields of the individual varieties are very irregular, and it is probable that other factors besides the extra time have influenced the yield, especially in the plots of the 3rd sowing.

Field Plots of Mangels.

The following five half-acre plots were all sown in the same field with the smaller plots reported on. The soil was similar and its preparation and treatment the same. These were all sown 6th May; came up 18th May, and the roots were pulled 24th to 26th October.

EXPERIMENTS WITH SUGAR BEETS.

Six varieties of sugar beets were tested in 1898. The land was a sandy loam, adjoining that used for the test plots of turnips, mangels and carrots. The soil was similar and the treatment, preparation and method of sowing was the same. Three sowings were made, the first on the 28th of April, the second on the 6th of May, and the third on the 21st of May, and after sowing, the same mixture of fertilizers that was used on the turnips was applied on the drills of the sugar beets, in the proportion of 500 pounds per acre. The roots were all pulled on the 13th of October, and the yield per acre has been calculated from the weight of roots obtained from two rows each 66 feet long.

In this instance, the advantage in crop has been with the later sowings.

A portion of each of the varieties of sugar beets were also left in the ground after the first lots were pulled, to gain information as to what advantage, if any, results from leaving the roots in the ground for a longer period. Six plots were so left until the 3rd of November, which allowed 21 days for additional growth, with the following results:—

EXPERIMENTS WITH POTATOES.

The report on the results of the tests made with varieties of potatoes will be found this year in the report of the Horticulturist, Mr. W. T. Macoun. The following table gives particulars of the results obtained from fifteen quarter-acre plots which were all grown adjoining each other in the same field. The land was similar throughout, and the preparation and treatment was the same for all. The soil was a light sandy loam, which was manured in the autumn of 1897 with about 12 tons of barn-yard manure per acre. The previous crop was hay. The land was ploughed in the spring of 1898, about 6 inches deep, and harrowed twice with the smoothing harrow, then made into drills 2½ feet apart and 6 inches deep for planting.

EXPERIMENTS WITH CLOVER.

The many experiments which have been conducted with clover at the Central Experimental Farm during the last four years have attracted much attention, especially those which have been made of sowing red clover with grain, and the ploughing under of the green clover crop late in the season to enrich the land. This subject has been much discussed, and by many the method recommended has been practised with manifest benefit.

Further trials have been made during the past season, and some very convincing results obtained as to the value of this green crop as a fertilizer when ploughed under.

On page 33 of the Annual Report of the Experimental Farms for 1897, reference was made to eight trial plots of grain grown that year of $\frac{1}{20}$ acre each, four of which had been sown with red clover, and the clover crop subsequently ploughed under, while on the other four plots the grain was sown without clover. Plots Nos. 1 and 2 had been sown with Preston wheat, Nos. 3 and 4 with Odessa barley (six-rowed), Nos. 5 and 6 with Bolton barley (two-rowed), and Nos. 7 and 8 with Banner oats. In each instance on one plot Red clover in the proportion of 10 pounds to the acre had been sown with the grain, while on the other plot the grain was sown without clover.

In October, 1897, this land was all ploughed about 8 inches deep, and in the spring of 1898 it was disc-harrowed and twice harrowed with the smoothing harrow, after which all the plots were sown with one variety of oats, the Banner. The oats were sown on the 27th of April and came up on the 6th of May. The difference in the growth of the grain on these plots was soon very noticeable, and as the season advanced, especially just before the heads appeared, the difference in height and vigour of growth in favour of the plots where the clover had been grown was very remarkable. So clearly was this manifest that the difference could be distinctly seen at a considerable distance, and the outline of those plots on which no clover had been grown could be readily traced by the manifestly shorter and less vigorous growth. After the grain was fully headed, the difference in appearance was not so clearly seen at a distance, but by a careful examination it could be easily traced. When ready to harvest the boundaries of the several plots were accurately marked, they were cut and threshed separately and the following particulars obtained :—

Results.	Straw, yield per Acre.	Oats, yield per Acre.	
	Lbs.	Bush.	Lbs.
Plot 1—On which Preston wheat was sown in 1897 with clover	3,770	56	6
Plot 2—After Preston wheat without clover	2,160	37	2
An increase in yield of oats after wheat on the plot with clover of 19 bushels 4 pounds per acre with an added weight of straw of 1,610 pounds.			
Plot 3—On which Odessa barley was sown in 1897 with clover	2,180	37	12
Plot 4—After Odessa barley without clover	1,450	30	10
An increase in yield of oats after barley on the plot with clover of 7 bushels 2 pounds per acre with an added weight of straw of 730 lbs.			
Plot 5—On which Bolton barley was sown in 1897 with clover	3,180	51	26
Plot 6—After Bolton barley without clover	2,090	44	24
Showing an increase in yield of oats after barley on the plot with clover of 7 bushels 2 pounds per acre with an added weight of straw of 1,090 lbs.			
Plot 7—On which Banner oats was sown in 1897 with clover	5,110	55	0
Plot 8—After Banner oats without clover	2,260	44	4
An increase in yield of oats after oats on the plot with clover of 10 bushels 30 pounds per acre with an added weight of straw of 2,850 pounds.			

The lower yields reported on plots 3 and 4 were due to the poor quality of the soil, which was a light sandy loam. The other plots alongside had a heavier sandy loam soil of much better quality.

The results of these tests are very encouraging, the average increase in the yield of grain on the four plots with clover being over 11 bushels per acre more than on those where no clover was used.

RESULTS OF GROWING INDIAN CORN AFTER CLOVER.

Favourable results have also been had from a series of plots on which Indian corn was planted after clover of different varieties and grown from different quantities of seed per acre had been ploughed under. These tests were conducted on 15 plots of $\frac{1}{20}$ acre each which were sown with a grain crop in 1897 when different sorts and

quantities of clover were sown with the grain, excepting plots 7, 10 and 12, which were left as check plots, on which the same sort of grain was sown, but without clover. The soil was a sandy loam of fair quality which received a dressing of about 12 tons of barn-yard manure per acre in the fall of 1896. No fertilizer has been applied since. In this case the clover was allowed to remain during the winter and to grow until the 23rd of May following, by which time most of the plots had made a heavy growth, when the land was all ploughed about 6 or 7 inches deep, and harrowed twice with the smoothing harrow before planting.

The variety of corn chosen for this test was the Longfellow, which was planted on the 25th of May with the seed drill in rows 3 feet apart, and was cut on the 15th of September. This corn made a medium and even growth of from 7 to 8 feet, was leafy from top to bottom, and the stalks were well eared, many of the ears then beginning to ripen. The following results were obtained :—

QUANTITY AND KIND OF CLOVER SOWN, 1897.

Plot.	Varieties of Clover Sown.	1898. Yield of Fodder Corn per Acre.	
		Tons.	Lbs.
1	Mammoth Red clover 4 lbs. per acre	15	560
2	" " " 6 lbs. "	15	1,720
3	" " " 8 lbs. "	15	1,440
4	" " " 10 lbs. "	15	1,360
5	" " " 12 lbs. "	16	1,920
6	" " " 14 lbs. "	17	1,860
7	Check plot, no clover sown	13	160
8	Common red clover, 10 lbs. per acre	22	200
9	Alsike clover, 6 lbs. per acre	15	640
10	Check plot, no clover sown	14	960
11	Alfalfa, 14 lbs. per acre	14	1,320
12	Check plot, no clover sown	13	280
13	Crimson clover, 24 lbs. per acre	14	20
14	Alsike, 6 lbs., Orchard grass, 14 lbs. per acre	19	200
15	Alfalfa, 6 lbs., Orchard grass, 14 lbs. "	14	1,280

These results clearly show the influence of the green clover as a fertilizer.

The beneficial effects on subsequent crops observed when clover is ploughed under is due largely to the fact that clover in common with most other leguminous plants has the power of taking nitrogen—one of the most valuable of fertilizers—from the air and laying this up in its roots and leaves, and when these are buried in the soil by ploughing the added fertility becomes available as plant food for subsequent crops. If a clover plant be dug there will be found attached to its fine branching roots many small nodules or swellings, each of which contains a colony of bacteria, and these microscopic organisms are the active agents employed in taking nitrogen from the air and converting it into plant food. Cultures are now made of these bacteria and sold under the name of Nitragin, to promote the growth of clover.

The extensive root system also which clover plants have, enables them to penetrate deeper in the soil than other plants, and to draw from the lower portions of the soil and subsoil other important constituents which growing plants require, and when the clover is turned under and decays, these also become available to after crops. Green crops when ploughed under also improve the texture of the soil by adding to it organic matter and thus make it more retentive of moisture and more suitable for sustaining plant growth.

RESULTS OF SOWING GRAIN WITH AND WITHOUT CLOVER.

Further experiments along this line have been tried during the past year at the Central Experimental Farm which furnish additional proof of the fact that the sowing of clover with grain does not affect the crop of grain for that year. The variations in yield shown in the series of results given below are no doubt due mainly to slight variations in the quality of the soil. The soil was a sandy loam of fair quality which was manured during the winter of 1896-97 with about 15 tons of barn-yard manure per acre. No fertilizer of any sort has been applied since. The previous crop was horse beans. The land was ploughed in the autumn of 1897, about 8 inches deep, disc-harrowed in the spring and harrowed twice with the smoothing harrow before sowing. The plots were all sown on the 27th of April, came up 6th of May, and was ripe from 25th to 30th of July. The wheat was sown at the rate of $1\frac{1}{2}$ bushels per acre; barley, six-rowed, $1\frac{3}{4}$ bushels; barley, two-rowed, 2 bushels; and oats, 2 bushels per acre. The wheat was ripe 30th July, six-rowed barley, 25th July, two-rowed barley and oats, 27th July.

WEIGHT OF CLOVER LEAVES, STEMS AND ROOTS PER ACRE.

Some further examinations were made during 1898 to ascertain the weight of the leaves and stems also of the roots per acre on land which had been sown with different quantities of seed. Such plots of the Mensury barley mentioned above as were sown with clover were chosen for this test. An area of 4 feet by 4 (16 square feet) was dug to the depth of 9 inches, and all the roots and tops of the clover carefully gathered and weighed, and the weight of the material thus collected formed the basis of the estimate of the weight per acre. These were dug on the 5th of November.

Plot 9. Mensury barley with 4 pounds Mammoth Red clover seed per acre:—

WEIGHT OF CLOVER LEAVES AND STEMS AND ROOTS ON PLOTS ALLOWED TO GROW UNTIL SECOND YEAR.

In the annual report of the Experimental Farms for 1897, page 37, reference is made to the weights of leaves and stems and roots per acre of clover in a series of plots ranging from Nos. 5 to 17, all of which were sown with Odessa barley on the 6th of May, 1897, with different quantities and kinds of clover; and on the 20th of October of that year the weight of the leaves, stems and roots were ascertained in the manner already explained and the results published in that report.

These plots were not ploughed in the autumn but the clover was left undisturbed until the 21st of May, 1898, by which time it had made a strong and heavy mat of growth and the plants had reached a height of nearly 2 feet.

Similar blocks to those already referred to, 9 inches deep and covering 16 square feet, were cut out of these plots on the 21st of May, when the following results were obtained :—

Plot 5. Sown with 4 pounds Mammoth Red clover seed per acre :—

Weight of Alfalfa leaves and stems per acre	3	816
" roots per acre	2	254
Total	5	1,070

Plot 17. Sown with 6 pounds Alsike clover per acre:—

	Tons.	Lbs.
Weight of clover leaves and stems per acre	11	631
" roots per acre	4	1,018
Total	15	1,649

These figures give much food for thought. They show an enormous increase in the useful fertilizing material which can be had, when clover is left over, for ploughing under in time for an Indian corn or potato crop, and indicate that the best results are likely to attend the pasturing of the clover in the autumn, and leaving it to be turned under in May following.

Thirty-six acres of field crops, chiefly oats and barley, were sown with clover last spring; the plants made good growth, although not quite so strong as in 1897 Nevertheless there was a fine mass of leaves, stems and roots turned under with the late autumn ploughing.

Results of Sowing Clover Seed Treated with Nitragin.

Experiments were tried during the past year in the sowing of clover seed inoculated with a culture of Nitragin. This material was obtained in bottles from the manufacturers, Messrs. Meister, Lucius & Bruning, of Germany. As received, the material was in a soft, gelatinous condition, easily liquified when slightly warmed. This was diluted with water in the manner and quantity directed and sprinkled on the clover seed which was subsequently dried, partly by exposure and partly with dry sand. Before treatment a definite weight of clover seed, sufficient for the experiments to be undertaken, was set aside for treatment, and a similar weight of the same lot of seed put by for use in the untreated condition. Each of these lots were divided into five portions, one of which was reserved for the trials to be made at the Central Farm, and the other four portions were sent to the branch farms.

The following are the results obtained at the Central Farm. The seed was sown on sandy loam on the 14th of June at the rate of 10 lbs. per acre. Both lots of seed germinated well and made good growth. On casual examination both looked very much alike as to strength and vigour, but on a more careful scrutiny the treated seed appeared to promise the best results.

On the 24th of November a piece of the soil 2 feet by 2 (8 square feet) and 9 inches deep was cut out of each plot, and the leaves, roots and tops carefully gathered, when the following particulars were obtained:

Plot 1. Seed inoculated with Nitragin:—

	Tons.	Lbs.
Weight of clover leaves and stems per acre	4	507
" " roots per acre	4	167
Total	8	674

Plot 2. Seed untreated:—

	Tons.	Lbs.
Weight of clover leaves and stems per acre	2	1445
" " roots per acre	2	760
Total	5	205

From this experiment it would appear that there may be a decided advantage in using Nitragin to inoculate the seed of clover under some conditions.

EXPERIMENTS WITH SOJA BEANS.

(Soja hispida.)

The Soja or Soya bean was first grown at the Central Experimental Farm as a fodder plant in 1897, when two varieties, a late and an early sort were tested. The early variety, the seed of which was obtained from Peter Henderson & Co., seedsmen, of New York, proved very promising and produced on the small plot grown a weight of fodder equal to 15 tons 855 lbs. per acre. In this case the beans were sown in rows 9 inches apart. Further experiments have been tried with this early ripening Soja bean during the past season, when two sets of plots were sown at different dates and of different widths in the rows with the object of finding out the best time to plant and the most profitable method of planting. The soil was a sandy loam of good quality, which received a dressing of fresh barn-yard manure of about twelve tons per acre, distributed in small piles of about one-third of a cart load each during the winter of 1897-98. This was spread in the spring. The previous crop was hay. The land was ploughed very lightly after the hay was taken off, and disc-harrowed and cultivated at intervals during the remainder of the season to keep down all growth. In the spring of 1898, the land was ploughed about 6 inches deep, and harrowed twice with the smoothing harrow before sowing. The beans were sown with the seed drill, from 1 to 2 inches apart in the rows.

Plot 1. Soja beans, sown in drills 35 inches apart. Sown 26th April, came up 14th May, and was cut for ensilage 12th September. The growth was strong and even, the plants were very leafy and grew to an average height of 42 to 46 inches, and they were very well podded. The beans in the pods were full-grown and beginning to harden at the time of cutting. The weight of green fodder was at the rate of 9 tons 520 pounds per acre.

Plot 2. Sown in drills 28 inches apart. Sown 26th April, came up 14th May, and was cut for ensilage 12th September. The growth was strong and even, the plants were very leafy and grew to an average height of 42 to 48 inches. They were very well podded, and the beans in the pods were full-grown and beginning to harden at the time of cutting. The weight of green fodder was 9 tons 890 pounds per acre.

Plot 3. Sown in drills 21 inches apart. Sown 26th April, came up 14th May, and was cut for ensilage 12th September. The growth was strong and even, the plants were very leafy and grew to an average height of 42 to 44 inches. They were very well podded, and the beans in the pods were full grown and beginning to harden at the time of cutting. The weight of green fodder was 10 tons 1,760 pounds per acre.

Plot 4. Sown in drills 21 inches apart. Sown 17th May, came up 31st May, and was cut for ensilage 12th September. The growth was strong and even, the plants were very leafy and grew to an average height of 42 to 44 inches. They were very well podded, and the beans in the pods were full grown and beginning to harden at the time of cutting. The beans appeared to be as far advanced in ripening in this plot as in those sown 26th April. The weight of green fodder was 11 tons 1,480 pounds per acre.

Pot 5. Sown in drills 14 inches apart. Sown 17th May, came up 31st May, and was cut for ensilage 12th September. The growth was strong and even, the plants were very leafy and grew to an average height of 42 inches. The plants were not as strong or woody in this plot as in the former; would have lodged very easily. They were fairly well podded and the beans were beginning to harden at the time of cutting. The weight of green fodder was 12 tons 1,800 pounds per acre.

Plot 6. Sown in drills 7 inches apart. Sown 17th May, came up 31st May, and was cut for ensilage 12th September. The growth was strong and even, the plants were very leafy and grew to an average height of 40 to 42 inches. The plants were not so strong or woody as where they were wider sown; would have easily lodged. They were fairly well podded, but the pods were not nearly as plentiful as when sown in rows 21 inches apart or as ripe at the time of cutting. The weight of green fodder was 12 tons 1,260 pounds per acre.

From these experiments it would appear that the best results may be looked for from planting these beans about the middle of May in drills 14 inches apart.

EXPERIMENTS WITH HORSE BEANS.

Two sets of plots were sown at different dates, and of different widths, during 1898. The soil was a sandy loam of good quality, which received a coating of barn-yard manure of about 12 tons per acre, distributed in small piles of about one-third of a cart load each, during the winter of 1897-98 which was spread in the spring. The previous crop was hay. The land was ploughed very lightly when the hay was taken off, and cultivated at short intervals afterwards to keep down all growth until autumn. In the spring of 1898, it was again ploughed about 6 inches deep, and harrowed twice with the smoothing harrow before sowing. The beans were sown with the seed drill.

Plot 1. Tick beans, imported seed. The seed on this plot was sown in rows 35 inches apart. Sown 26th April, came up 14th May, and was cut 25th August. The growth was weak and even. Height 30 to 38 inches. Blight was first noticed on the leaves on 27th July, and spread so rapidly that all the plots had to be cut on 26th August. Yield per acre, 2 tons 340 pounds.

Plot 2. Seed sown in rows 28 inches apart. Sown 26th April, came up 14th May, and was cut 25th August. The growth was weak and even. Height 30 to 38 inches. Yield per acre, 2 tons 340 pounds.

Plot 3. Seed sown in rows 21 inches apart. Sown 26th April, came up 14th May, and was cut 25th August. The growth was weak and even. Height 30 to 38 inches. Yield per acre, 2 tons 1,940 pounds.

Five additional plots were sown adjoining the first three. The soil was similar, and the preparation and treatment of the land the same.

Plot 4. Seed sown in rows 35 inches apart. Sown 17th May, came up 31st May, and was cut for ensilage 12th September. The growth was weak and even. Height 36 to 40 inches. Well podded, and a large proportion of the beans ripe. Yield per acre, 4 tons 1,840 pounds.

Plot 5. The seed on this plot was sown in rows 28 inches apart. Sown 17th May, came up 31st May, and was cut for ensilage 12th September. The growth was weak and even. Height 36 to 40 inches, well podded, and a large proportion of the beans ripe. Yield per acre, 4 tons 1,360 pounds.

Plot 6. The seed was sown in rows 21 inches apart. Sown 17th May, came up 31st May, and was cut for ensilage 12th September. The growth was weak and even. Height 36 to 40 inches, well podded, and a large proportion of the beans were ripe. Yield per acre, 3 tons 1,730 pounds.

Plot 7. The seed was sown in rows 14 inches apart Sown 17th May, came up 31st May, and was cut for ensilage 12th September. The growth was weak and even. Height 36 to 40 inches, fairly well podded, not as many as on plot 3, beans beginning to ripen. Yield per acre, 3 tons 1250 pounds.

Plot 8. The seed was sown in rows 7 inches apart. Seed sown and cut for ensilage on same dates as No. 7. The growth was weak and even. Height 36 to 40 inches. There were very few pods. Pods beginning to ripen. Yield per acre, 2 tons 1,730 pounds.

Field Plots of Horse Beans.

Two field plots of half an acre each were sown with horse beans during 1898. The soil was a heavy sandy loam of good quality, partly clay, which was manured in the autumn of 1894 with about 18 tons of barn-yard manure per acre. No fertilizer has been applied since. The previous crop was oats. It was ploughed in the autumn of 1897, about 8 inches deep, and in the following spring it was disc-harrowed once, and harrowed twice with the smoothing harrow before sowing. The beans were sown with the grain drill in rows 3 feet apart, using about 50 pounds of seed per acre.

Plot 1. One half acre. Tick beans, imported seed. Sown 26th April, came up 14th May, and was cut for seed 22nd August. The growth was weak and even, vines fairly well podded, pods quite ripe. Height 30 to 33 inches. Blight was first

noticed on the leaves 27th July, and spread so rapidly up to 22nd August, that all had to be then cut. Yield per acre, 3 tons 304 pounds; yield of seed per acre, 10 bushels 72 pounds.

Plot 2. One-half acre. This was adjoining plot 1, on similar soil and the land had similar preparation and treatment. The seed was also of the variety known as Tick, but of Canadian growth. Sown 26th April, came up 14th May, and was cut for seed 22nd August. The growth was weak and even, vines fairly well podded, pods quite ripe. Height 30 to 33 inches. Blight was first noticed on the leaves 27th July. Yield per acre, 3 tons 740 pounds; yield of seed per acre, 9 bushels 8 pounds.

EXPERIMENTS WITH SUNFLOWERS.

Two field plots covering 1 acre were sown with this crop. The soil was a heavy sandy loam, partly clay, of good quality, which was manured in the autumn of 1894 with about 18 tons of barn-yard manure per acre. No fertilizer has been applied since. The previous crop was oats. It was ploughed in the autumn of 1897, about 8 inches deep, and in the following spring it was disc-harrowed once, and harrowed twice with the smoothing harrow before sowing. The seed was sown with the grain drill in rows 3 feet apart, using 3 to 4 pounds of seed per acre, and the plants were thinned out when they were 3 or 4 inches high so as to leave them from 18 to 20 inches apart in the rows.

Plot 1. One-half acre. Mammoth Russian Sunflowers, black seeded variety. Sown 26th April, came up 11th May, and the heads were quite ripe when cut for the silo on 9th September. The plants were of medium growth, and the yield of heads was 5 tons 970 pounds per acre.

Plot 2. One-half acre. Mammoth Russian Sunflowers, light coloured seed. Sown 26th April, came up 11th May, and the heads were quite ripe when cut for the silo on 9th September. The plants were of medium and even growth. Yield of heads per acre, 5 tons 990 pounds.

EXPERIMENTS WITH FLAX.

The experiments which were begun with flax in 1896 to gain information as to the best time for sowing and the quantity of seed which should be sown to give the heaviest crops, have been continued. The soil was a sandy loam of medium quality, rather heavy, which was manured during the winter of 1896–97 with about 15 tons of barn-yard manure per acre. The previous crop was horse beans. The land was ploughed in the autumn of 1897, about 8 inches deep, and in the following spring it was disc-harrowed once and harrowed twice with the smoothing harrow before sowing.

FIRST SOWING.

Plot 1. Forty pounds of seed per acre. Sown 25th April, came up 8th May, and was ripe 29th July. Made a strong and even growth, all standing well.

Weight of straw per acre.......................... 3,200 pounds.
Yield of seed per acre.......................... 13 bushels 12 pounds.

Plot 2. Eighty pounds of seed per acre. Seed sown and ripened on same dates as plot 1. Made a strong even growth, all standing well.

Weight of straw per acre.......................... 3,390 pounds.
Yield of seed per acre.......................... 13 bushels 42 pounds.

SECOND SOWING.

Plot 3. Forty pounds of seed per acre. Sown 2nd May, came up 11th May, and was ripe 29th and 30th July. Made a medium and even growth, all standing well.

Weight of straw per acre.......................... 2,960 pounds.
Yield of seed per acre.......................... 9 bushels 16 pounds.

Plot 4. Eighty pounds of seed per acre. Seed sown and ripe on same dates as plot 3. Made a strong and even growth, all standing well.

Weight of straw per acre.......................... 3,260 pounds.
Yield of seed per acre.......................... 11 bushels 44 pounds.

THIRD SOWING.

Plot 5. Forty pounds of seed per acre. Sown 9th May, came up 17th May, and was ripe 6th August. Made a medium and even growth, all standing well.

Weight of straw per acre........................2,880 pounds.
Yield of seed per acre.......................8 bushels 32 pounds.

Plot 6. Eighty pounds of seed per acre. Seed sown and ripe on same dates as plot 5. Made a medium and even growth, all standing well.

Weight of straw per acre........................2,580 pounds.
Yield of seed per acre.....................12 bushels 18 pounds.

FOURTH SOWING.

Plot 7. Forty pounds of seed per acre. Sown 16th May, came up 23rd May, and was ripe 9th August. Made a medium and even growth, all standing well.

Weight of straw per acre........................2,150 pounds.
Yield of seed per acre.......................7 bushels 18 pounds.

Plot 8. Eighty pounds of seed per acre. Seed sown and ripe on same dates as plot 7. Made a medium and even growth, all standing well.

Weight of straw per acre........................2,630 pounds.
Yield of seed per acre.....................11 bushels 54 pounds.

These four sets of plots were sown a week apart, beginning with the 25th of April. On the first plot in each group 40 pounds of seed were used, and on the second 80 pounds. The heaviest weights both of seed and straw have been obtained from the earliest sown plots.

SPECIAL EXPERIMENTS WITH FERTILIZERS.

In the annual report of the Experimental Farms for 1893, details were given on pages 8 to 24 of the results of a series of tests which were carried on during the previous five or six years with the object of gaining information regarding the effects which follow the application of certain fertilizers and combinations of fertilizers on the more important farm crops. The particulars there given covered the results of six years' experience with crops of wheat and Indian corn, and five years' experience with crops of oats, barley, turnips and mangels. The results of similar tests conducted for three years with carrots and one year with sugar beets were also given.

These experiments have been continued; and as explanatory regarding the preparations made and the general plan, together with the way in which they have been carried on, the following paragraphs are quoted from the report of 1893 :—

"A piece of sandy loam, more or less mixed with clay, which was originally covered with heavy timber, chiefly white pine, was chosen for these tests. The timber was cut many years ago, and among the stumps still remaining when the land was purchased, there had sprung up a thick second growth of trees, chiefly poplar, birch and maple, few of which exceeded 6 inches in diameter at the base. Early in 1887, this land was cleared by rooting up the young trees and stumps and burning them in piles, on the ground from which they were taken, the ashes being afterwards distributed over the soil as evenly as possible, and the land ploughed and thoroughly harrowed. Later in the season it was again ploughed and harrowed, and most of it got into fair condition for cropping.

"The plots laid out for the experimental work with fertilizers were one-tenth of an acre each, 21 of which were devoted to experiments with wheat, 21 to barley, 21 to oats, 21 to Indian corn or maize, and 21 to experiments with turnips and mangels. It was not practicable to undertake work on all the plots the first season. The tests were begun in 1888 with 20 plots of wheat and 16 of Indian corn, and in 1889 all the series

were completed excepting six plots of roots, Nos. 16 to 21 inclusive, which were available for the work in 1890." In all cases the plots in each series have been sown on the same day.

"In 1890 it was found that all the grain plots had become so weedy that the growth of the crops was much interfered with, and with the view of cleaning the land one-half of each of the wheat and oat plots was sown with carrots in 1891, and one-half of each of the barley plots with sugar beets. In 1892 the other half of each plot in each of these series was sown with carrots. In 1893 it was thought desirable to continue this cleaning process, and carrots were again sown on the half of the wheat and oat plots occupied with this crop in 1891, and also on the half of the barley plots cropped with sugar beets that year." In 1894, 1895, 1896, 1897 and 1898 the one-half of the oat plots were sown again with carrots and the half of the plots devoted to wheat and barley were planted with potatoes.

TREATMENT OF SOIL.

"The treatment of the soil on all the grain plots has been to gang-plough soon after harvest, and after the shed grain and weeds have well started to plough again later, about 7 inches deep. In spring the plots have been gang-ploughed once before applying the fertilizers, which are then scattered over the surface and harrowed with the smoothing harrow before sowing. On those plots where barn-yard manure has been used, the manure has been lightly ploughed under as soon as possible after it has been spread on the land and just before sowing. Wherever barn-yard manure is spoken of, it is understood to be a mixture of horse and cow manure in about equal proportions."

A summary of these permanent fertilizer plots is given each year, taking the average yield of the whole of the previous period, adding the results of the current year, and then giving the average yield for the full time.

CHANGES IN THE FERTILIZERS USED.

Ten years' experience has shown that the finely ground untreated mineral phosphate is of no value as a fertilizer. This substance has been heretofore used every year on wheat, on plots 4, 5, 6, 7 and 8, also on the plots similarly numbered in the experiments with fertilizers on barley, oats, Indian corn, carrots and potatoes, and in the experiments on roots on plots 4, 5, 6 and 7. In all these plots the use of the finely ground untreated mineral phosphate has been discontinued this year and in its place similar weights of the Thomas' phosphate powder used.

WHEAT PLOTS.

The seed sown on each of these plots from the beginning has been in the proportion of 1½ bushels per acre, excepting in 1894; and the varieties used were as follows: In 1888-89-90 and 1891 White Russian, and in 1892-93 Campbell's White Chaff. In 1894 the Rio Grande wheat was used, and shortly before sowing it was tested as to vitality and found to be deficient in germinating power,—less than half the kernels sprouted. As it was not practicable then to secure better seed, double the usual quantity was sown, namely, three bushels per acre, which gave a proportion of growth on each plot of about the usual thickness. In 1895, 1896, 1897 and 1898 Red Fife wheat was used in the usual quantity of 1½ bushels per acre. In 1898 the Red Fife was sown 27th April, came up 8th May and was harvested 4th August, requiring from the date of sowing to maturity a period of 99 days.

The season of 1898 at Ottawa has been fairly good for the growing of spring wheat, and has given in general, crops above the average. In the plots referred to in the following table, those treated with barn-yard manure have exceeded the average of past years, all the others have fallen below it.

BARLEY PLOTS.

The quantity of seed sown per acre on the barley plots was 2 bushels in 1889, 1890 and 1891, $1\frac{1}{2}$ bushels in 1892 and 1893, and 2 bushels in 1894, 1895, 1896, 1897 and 1898. Two-rowed barley has been used for seed throughout the whole period. The varieties used were as follows: 1889, 1890 and 1891, Saale; 1892, Goldthorpe; 1893, Duck-bill; and in 1894, 1895, 1896, 1897 and 1898, Canadian Thorpe, a selected form

of the Duck-bill. In 1898 the Canadian Thorpe was sown on 28th April, came up 8th May and was harvested 8th August, requiring from the date of sowing to maturity a period of 102 days.

In 1898 the yield of all the barley plots has been less than the average of past seasons, excepting the two plots fertilized with barn-yard manure, which have exceeded the average.

OAT PLOTS.

The quantity of seed sown per acre on the oat plots, was 2 bushels in 1889 and 1890; $1\frac{1}{2}$ bushels in 1891, 1892 and 1893, and 2 bushels in 1894, 1895, 1896, 1897 and 1898. The varieties used were as follows: In 1889, Early English; 1890, 1891, 1892, 1893, Prize Cluster; and in 1894, 1895, 1896, 1897 and 1898, Banner. In 1898 the Banner was sown 27th April, came up the 8th May, and was harvested 1st August, requiring from the date of sowing to maturity a period of 96 days.

In 1898, the crops from plots 1, 2 and 6 on which barn-yard manure was used were all considerably above the average. This year plot 1, on which rotted manure was used, has given 30 pounds of oats more per acre than that of plot 2 where the manure was applied in a fresh condition. The crop of plot 2 has, however, during the ten years' test given an average of 6 bushels 3 pounds per acre more than plot 1. Of the

other plots, treated with chemical fertilizers, all have fallen much short of the results obtained from barn-yard manure. Seven of them have given returns a little above the average, while 11 have fallen below the average of past years.

CORN PLOTS.

The experiments with the plots of Indian corn have been conducted with the object of obtaining the largest weight of well matured green fodder for the silo, and to have the corn so far advanced when cut, that the ears shall be as far as is practicable in the late milk, or glazed condition. Each plot has been divided from the outset into two equal parts, on one of which—known as No. 1—one of the stronger growing and somewhat later ripening sorts has been tried, and on the other, marked No. 2, one of the earlier maturing varieties. During the first four years one of the Dent varieties was tested under No. 1. The Mammoth Southern Sweet was tried in 1888, 1889 and 1890. In 1891 the Red Cob Ensilage was used, and in 1892, 1893, 1894, 1895, 1896, 1897 and 1898 a free growing Flint variety, the Rural Thoroughbred White Flint, was tested. On the other half of the plot (No. 2) the Canada Yellow Flint was used in 1888, 1889 and 1890, the Thoroughbred White Flint in 1891, Pearce's Prolific in 1892, 1893 and 1894, and the Mammoth Eight Rowed Flint in 1895, 1896, 1897 and 1898. For the first four years the No. 1 series was planted in drills 3 feet apart, using about 24 pounds of seed to the acre and thinning the plants, when up, to 6 or 8 inches, and the No. 2 in hills 3 feet apart each way and 4 or 5 kernels in a hill. During the past seven years both sorts have been grown in hills. The corn in both series of plots was planted in 1898 on 16th May, and cut 15th September. In most instances the yield of fodder on these plots during the past season has been below the average of past years.

With Indian corn the rotted manure has given in both plots a slightly larger return this year than the fresh manure, but the average of ten years' tests still shows the fresh manure in advance of the rotted in plot 1 by 1 ton 484 pounds per acre, while in plot 2 the advantage is with the rotted manure by 1,911 pounds per acre.

PLOTS OF MANGELS AND TURNIPS.

In conducting these experiments the roots only have been taken from the land, the tops have always been cut off and left on the ground to be ploughed under so that the plant food they have taken from the soil may be returned to it. One-half of each one-tenth acre plot in the series has been devoted to the growth of mangels, and the other half to turnips, and these crops have been alternated from year to year. The preparation of the land has been the same for both these roots. It was ploughed in the autumn after the crop is gathered, gang-ploughed deeply in the spring after the barn-yard manure has been spread on plots 1, 2 and 6, and after gang-ploughing the other fertilizers were spread by scattering them evenly over the surface, after which it was all harrowed with the smoothing harrow, then made in ridges 2 feet apart, rolled and sown.

In 1889, the variety of mangel used was the Mammoth Long Red. In 1890, three varieties were sown: 15 rows of Mammoth Long Red, 6 of Mammoth Long Yellow, and 6 of Golden Intermediate on each plot. In 1891, each plot again had three varieties: 18 rows of Mammoth Long Red, 3 of Yellow Fleshed Tankard, and 6 of Golden Tankard. In 1892, 1893, 1894, 1895, 1896, 1897 and 1898, one variety only was used, namely, the Mammoth Long Red. About 4 pounds of seed have been sown per acre, each year. In 1898 the mangels were sown 5th May, came up 15th May, and were pulled 17th October.

Two varieties of turnips were sown on the half plots devoted to these roots in 1889: 25 rows of Carter's Prize Winner, and 2 rows of Carter's Queen of Swedes, and in 1890, a single variety, Carter's Elephant Swede. In 1891, six varieties were sown: 6 rows of Lord Derby Swede, 4 of New Giant King, 3 of Imperial Swede, 6 of Champion Swede, 4 of Purple Top Swede, and 4 of East Lothian Swede. In 1892, the Improved Purple Top Swede only was sown, in 1893 and 1894 the Prize Purple Top Swede, in 1895 the Imperial Swede, and in 1896, 1897 and 1898 the Prize Purple Top Swede. The land used for the turnips, which are usually sown later than the mangels, is prepared in the same manner and the fertilizers are spread on it at the same time as they are for the mangels. It is then allowed to stand until the day before sowing, then gang-ploughed shallow or cultivated to kill weeds and loosen the soil, ridged, rolled and sown. In 1898, the turnips were sown 10th May, came up 17th May, and were pulled 18th October. The rotted manure has averaged better results throughout than the fresh manure with the mangels, but the turnips have given better results with the fresh manure.

CARROT PLOTS.

Carrots have been sown on alternate halves of the oat plots for the past seven years, for the purpose of cleaning the land from weeds. This work was begun in 1891, and the plots have been sown each year with the variety known as the Improved Short White. In 1898, carrots occupied the west half of the plots. The seed was sown 27th April, came up 15th May, and the roots were pulled 21st October. The crop this year has been comparatively light and all the plots have been below the average in yield.

* This plot was on a ridge and the soil being sandy, many of the plants were destroyed in 1898 by a wind storm.

POTATO PLOTS.

The alternate halves of the wheat and barley plots which were occupied by carrots and sugar beets in 1891, 1892 and 1893 were planted with potatoes in 1894, 1895, 1896, 1897 and 1898. These were planted in rows 2½ feet apart, with the sets about one foot apart in the rows.

Those grown in 1898 after wheat, were planted 14th May, came up 1st June, and were dug 22nd September. On each of these plots there were nine rows each of Empire State, Early Sunrise and Clarke's No. 1.

Those grown after barley, were planted 12th May, came up 21st May, and were dug 19th September. On these plots there were nine rows each of Vanier, Lee's Favourite and Northern Spy. In the tables following, the yield of each variety for each plot is given, also the crop, in bushels, per acre.

In the following table particulars are given of the crops of potatoes obtained each year from 1894 to 1898, inclusive, from each of the plots devoted to experiments with fertilizers, also the average results of these tests for five years. It will be seen that plot 1, to which well rotted barn-yard manure has been applied, has given the best average results in the plots after barley, while in those after wheat plot 2 on which fresh manure was used, has the advantage. None of the artificial fertilizers or mixtures of these fertilizers have given results as good as those obtained from barn-yard manure. Of the single fertilizers tried, the best crops have been had from the mineral superphosphate of lime, and the next best from muriate of potash.

The varieties which have been tested during the five years named and the weights obtained of each sort in pounds per row are here given. These rows have in each case run through the whole series of fertilized and check plots, and as the conditions under which the different varieties have been grown may be considered as very similar, if not identical, the results may fairly be regarded as indicating the relative productiveness of the different sorts under trial.

DISTRIBUTION OF SEED GRAIN.

Another distribution of seed grain was made in the spring of 1898, consisting mainly of samples of the most promising varieties which were grown at the several experimental farms. These were sent to farmers on application one sample only to each applicant. The object of this distribution was to place within reach of farmers for the improvement of seed, pure samples and true to name of the best and most productive sorts in cultivation. By the careful handling of these samples any farmer can soon obtain sufficient seed for a large area and may thus be provided with the best sorts of grain without any cost beyond that of his own labour. That this part of the farm work is appreciated by farmers throughout the Dominion is shown by the very large demand each year for samples.

Preparations have been made for another distribution in 1899 which will consist as heretofore of the most promising sorts of oats, barley, wheat, pease, Indian corn and potatoes. The several branch farms will also again distribute samples to farmers residing in the provinces and territories where these farms have been established.

The samples sent out from the Central Experimental Farm at Ottawa during the early months of 1897 were distributed as follows :—

Kind of Grain.	Prince Edward Island.	Nova Scotia.	New Brunswick.	Quebec.	Ontario.	Manitoba.	North-west Territories.	British Columbia.
Oats	426	932	1,235	3,858	2,471	741	492	96

DISTRIBUTION OF SAMPLES FROM THE BRANCH EXPERIMENTAL FARMS.

Samples of three pounds each were also distributed from the branch experimental farms as follows :—

Experimental Farm, Nappan, N. S.

Oats	232
Barley	122
Wheat	137
Pease	93
Buckwheat	13
Rye	4
Potatoes	385
	986
No. of applicants supplied	533

Experimental Farm, Indian Head, N.W.T.

Oats	332
Barley	182
Wheat	177
Pease	205
Flax	10
Rye	11
Potatoes	381
	1,298

Experimental Farm, Brandon, Man.

Grain of all sorts	361
Potatoes	129
	490

Experimental Farm, Agassiz, B.C.

Oats	61
Barley	29
Wheat	43
Pease	47
Potatoes	137
	317

These samples added to the number distributed by the Central Experimental Farm make a total of 34,970. This distribution has awakened much interest among farmers regarding the choice of better varieties for seed, and many of the more productive sorts are by this means fast finding their way into general cultivation.

TESTS OF THE VITALITY OF GRAIN AND OTHER SEEDS FOR 1898.

The number of samples of seed grain and other seeds which were tested during the season of 1898 to ascertain the proportion which would germinate was 1,834. The following figures show the variations in the average vitality of the more important cereals during the past six years.

	1893.	1894.	1895.	1896.	1897.	1898.	Average for the Six Years.
Wheat	81·8	90·5	88	87·7	83·5	86·4	86·3
Barley	84·9	89	85·7	90·1	90	91·3	88·5
Oats	93	95·5	93·3	89·8	93·6	92·4	92·9

Many of the samples sent for test are much below the average in vitality and on this account the figures given do not fairly represent the vitality of grain of average quality grown in different parts of the Dominion. The chief object in continuing these tests from year to year is to give farmers the opportunity of having any samples which may be of doubtful vitality, through injury during harvesting or storing, thoroughly tested so that their value for seed purposes may be known. Samples may be sent free through the mail,—the quantity of grain sent should not be less than one ounce,—and this work is done and reported on free of charge. The vitality of samples can usually be ascertained within a fortnight after they are received.

RESULTS of Tests of Seeds for Vitality, 1897-98.

									24·75	112·25	183		

Rain or snow fell on 183 days during the 12 months.
Heaviest rainfall in 24 hours, 1·12 inches on October 22nd.
Heaviest snowfall in 24 hours, 12·00 inches on February 21st.
It will be seen the highest temperature during the 12 months was 95°·0 on July 3rd.
The lowest temperature during the 12 months was—24°6 on January 30th.
During the growing season rain fell on 9 days in April, 14 days in May, 13 days in June, 12 days in July and 16 days in August.
April shows the lowest number of days on which rain fell, viz., 9.
Rain or snow fell on 22 days during December.
Total precipitation during the 12 months 37·17 inches, as compared with 33·08 inches during 1897.

WILLIAM T. ELLIS, *Observer.*

LIVE STOCK

AT THE

CENTRAL EXPERIMENTAL FARM.

The live stock at the Central Experimental Farm consists of the following animals:

HORSES.

Of these there are fourteen in all, eight of which form the four working teams of the farm. Of the other horses two are used principally as drivers and the other four for miscellaneous work, including omnibus service. This vehicle which carries the mails, also passengers to the city, makes three trips each day, which requires the services of three horses in order to provide for the necessary changes in the team from day to day. Most of these horses have now been in use for about eleven years, and hence have reached an age when they cannot be expected to render profitable service much longer. It is expected that they will gradually be replaced with younger animals as soon as they begin to fail to do useful and satisfactory work. No horses are now kept for breeding purposes.

CATTLE.

The cattle comprises in all thirty-eight animals, four of which are bulls, twenty-two cows, five heifers and seven heifer calves. There are also thirty-two steers which were bought in the autumn from farmers in the neighbourhood of Ottawa for the purpose of carrying on feeding tests, with different sorts and combinations of fodders, grain and other concentrated food products, to gain information as to the most economical methods to follow in the feeding of steers. These will be sold for beef in the spring.

Part of the milk from the cows is sold to the residents on the farm and the remainder delivered to the dairy where it is made into butter and disposed of at market prices; the skim-milk being used for calves and pigs. The bulls are kept partly for their use on the farm and are available also to farmers at very moderate charges for the improvement of stock.

The cattle may be grouped as follows:—

Guernseys—1 bull, 4 years.
1 heifer calf.
Ayrshires —1 bull, 1½ years.
1 heifer, 3 years.
Jerseys — 1 bull, 1½ years.
2 heifers, 3 and 2 years.
Shorthorns—1 bull, 3 years.
Canadians—6 cows, varying in age from 3 to 11 years.
1 heifer calf.
Grades —16 cows of different ages from 3 to 12 years.
2 heifers, 2 years.
5 heifer calves.

In October, 1898, these animals were again tested with tuberculine and all were found to be quite free from disease.

SWINE.

The following is a summary of the pigs in stock on 30th November, 1898:—

Yorkshires—1 boar, 2 years.
1 sow, 3 "
1 " 5 months.

Berkshires—1 boar, 2½ years.
1 sow, 3 "
1 " 6 months.

Tamworths—1 boar, 1 year.
1 sow, 3 years.
1 " 2 "
1 " 6 months.

Poland Chinas—1 boar, 3 years.
1 sow, 3 "
1 " 6 months.

Chester Whites—1 boar, 2 years.
1 sow, 3 "

Grades—8 pigs, 6 months.
13 " 4 "

POULTRY.

The total number of birds on hand in the poultry houses was 240, and consisted of the following:—14 cocks, 18 cockerels, 149 hens, 52 pullets, 2 drakes, 4 ducks and 1 gander.

The following are the breeds represented and the number of each:—

White Leghorns—2 cocks, 3 cockerels, 24 hens, 8 pullets.
Black Minorcas—3 cocks, 4 cockerels, 7 hens, 8 pullets.
White Minorcas—1 cock, 2 hens, 7 pullets.
Andalusians—1 cock, 2 cockerels, 10 hens.
Brown Leghorns—1 cock, 8 hens.
Light Brahmas—1 cock, 7 hens.
Langshans—3 cockerels, 8 hens, 8 pullets.
Silver-laced Wyandottes—9 hens.
White Wyandottes—10 hens.
Barred Plymouth Rocks—3 cocks, 3 cockerels, 21 hens, 8 pullets.
White Plymouth Rocks—1 cock, 3 cockerels, 8 hens, 8 pullets.
Coloured Dorkings—1 cock, 7 hens.
Cross-breds—28 hens.
Pekin Ducks—1 drake, 3 ducks.
Aylesbury Ducks—1 drake, 1 duck.
1 Wild Goose, male.

APIARY.

In the apiary there are 55 colonies of bees.

EXPERIMENTS IN THE FEEDING OF STEERS, 1897-98.

Twenty-two steers, divided into 11 groups of two each, have been fed with different kinds of fodder mixtures and feeds at the Central Experimental Farm during the past year. The feeding period was divided into four equal portions of four weeks each, making sixteen weeks in all. The bulky fodder rations have been varied, but the particulars of their combination will be found at the head of each group. The meal referred to in the tables has been made of equal parts by weight of pease, barley and oats. In

estimating the cost of the rations, the mixed meal has been valued at the uniform rate of one cent per pound, corn ensilage at $2 per ton, roots $2 per ton, hay at $8 per ton, and straw at $4 per ton. Bran has been valued at $10 per ton, and ground oil-cake and cotton seed meal each at $25 per ton. The price of these products will vary in different localities and in different seasons, but the figures given are about the cost of production or purchase at Ottawa and will afford a basis of comparison for other parts of the Dominion.

In the feeding of farm animals with combinations of fodders and grain, it is desirable to know how far such rations conform to the standard known as a *balanced ration* in each case. In estimating the food value of a ration it is considered mainly from the relative proportions it contains:

1st. Of protein or nitrogenous matter, the function of which is to build up, to supply the nitrogen compounds required for satisfactory growth and at the same time furnish material for repairing and keeping in healthy action the working machinery of the body, and, in the case of milch cows, to provide for an ample secretion of milk.

2nd. Of carbo-hydrates and fat. These, although quite distinct in their character, are conveniently grouped together when considering their feeding value. The carbohydrates consist of such materials as starch, sugar and gum, together with fibre, the woody portions of the plant. These form the largest part of vegetable foods and when digested are either converted into fat or used to produce heat and energy in the body. Fat taken into the animal economy serves a similar purpose to that of the carbohydrates, but is more effectual, one part of fat being equal to 2¼ parts of carbohydrates.

In estimating the value of a ration for any particular class of animals, the proportion of protein it contains is compared with the carbo-hydrates and fat added; the amount of fat having, as already stated, been multiplied by 2¼, and the relation which the protein bears to the carbo-hydrates and fat is known as the nutritive ratio, and a food is said to be a balanced ration when it contains the nutritive materials referred to in about the proportions which experience has shown to produce the best results.

A ration with a large proportion of carbo-hydrates and fat as compared to its protein, is said to have a wide nutritive ratio, while one having a relatively small proportion of carbo-hydrates is spoken of as having a narrow nutritive ratio.

With the object of making this matter clear and of enabling those who desire to ascertain for themselves the nutritive ratio of any foods or combinations of foods they may desire to use, a list is submitted of such coarse fodders, grain and other feeding materials as are commonly used by farmers and stockmen, with the proportions of dry matter in each pound, also the digestible protein, digestible carbo-hydrates and fat, total digestible constituents and nutritive ratio all in adjoining columns. These figures correspond with those given by Prof. W. A. Henry, of Wisconsin, in his recent book on "Feeds and Feeding" which is now generally accepted as a reliable guide on this subject.

Name.	Total Dry Matter in each Lb.	Protein.	Carbo-hydrates + (fat × 2·25).	Total.	Nutritive Ratio.

Sugar Beets	·13	·011	·104	·115	1: 9·4
Potatoes	·21	·009	·165	·174	1:18·3
Ensilage (Corn)	·21	·009	·129	·138	1:14·3
SOILING FODDER.					
Fodder Corn	·20	·010	·125	·135	1:12·5
Pease and Oats	·16	·018	·076	·094	1:4·2
Pease and Barley	·16	017	·077	·094	1:4·5
Red Clover	·29	·029	·164	·193	1:5·6
Alfalfa	·28	·039	·138	·177	1:3·5

The figures forming the nutritive ratio are obtained by dividing the carbo-hydrates and fat by the protein. As an illustration as to how this table may be used to ascertain the nutritive ratio in any fodder mixture, let us take the bulky fodder ration No. 1 used in the feeding experiments to be presently referred to:

—	Dry Matter.	Protein.	Carbo-hydrates and Fat.	Total.	Nutritive Ratio.
50lbs. Corn ensilage	10·50	·450	6·450	6·900	
25lbs. Roots (mangels)	2·25	·275	1·400	1·675	
5lbs. Clover hay, cut	4·25	·340	1-980	2·320	
5lbs. Oat straw, cut	4·55	·060	2·020	2·080	1:10·5

This ration is rather wide to obtain the best results, but it is easily made narrower by the addition of grain and other concentrated feeds—3 pounds of meal, equal parts of oats, barley and pease with 1 pound of oil-cake or cotton seed meal fed to each animal per day, with an average consumption of 40 pounds of coarse fodder per day, will narrow the ration down to about 1:7·2, whereas the accepted standards for the feeding of young steers range from 1:6 to 1:8.

The amount of dry matter in the food would, however, in this case be short of the quantity said to give the best results, but this could be increased by adding to the quantity of hay consumed, which would again widen the ration somewhat and require a further addition of grain or bran to correct this.

The objects in view in conducting these experiments have been to gain such information as will show how beef can be produced at the smallest cost, how such products as the farmer can easily grow may be used to the best advantage, and what results are had where rations are fed the nutritive ratio of which is wider than is usually recommended.

No strict uniformity in results can be expected even where the same ration is fed: the breeding of the animal, its individual vigour and capacity for digestion, the temperature of the stables, and the quality of the food where ensilage forms any considerable part of it, are all factors which influence the results to a considerable degree, neverthelesss much useful information may be gained by repeated tests of this character which will be helpful to farmers and stockmen.

During the course of these tests the steers were given all the bulky fodder they would eat up clean, they were watered regularly twice a day and supplied with salt in a small box at the side of the manger.

The steers were weighed on the 18th December and again three times at the close of the period of preparatory feeding on the 18th January. The first weights taken and the average of the three last weighings were as follows, the weights being given in the order in which the animals were finally grouped:—

WEIGHT OF STEERS.

The eleven groups of steers referred to in the adjoining tables were fed as follows :—

GROUP No. 1.—TWO STEERS, NOS. 1 AND 2.

Bulky fodder ration No 1.—

Ensilage, 50 lbs..............1st 4 weeks, no meal.
Turnips, 25 lbs.,.............2nd 4 weeks, no meal.
Hay, cut, 5 lbs..............3rd 4 weeks, 2 pounds meal per day.
Straw, cut, 5 lbs,............4th 4 weeks, 6 pounds meal per day.

Nutritive ratio : 1st and 2nd 4 weeks, 1:10·5 ; 3rd 4 weeks, 1:8·9 ; 4th 4 weeks, 1:7·5.

GROUP No. 2.—TWO STEERS, NOS. 3 AND 4.

Bulky fodder ration No 1.—

1st 4 weeks, no meal.
2nd 4 weeks, 1 lb. meal and 1 lb. cotton seed meal per day.
3rd 4 weeks, 2 lbs meal and 2 lbs cotton seed meal per day.
4th 4 weeks, 4 lbs meal and 2 lbs cotton seed meal per day.

Nutrtive ratio : 1st 4 weeks, 1:10·5 ; 2nd 4 weeks, 1:6·6 ; 3rd 4 weeks, 1:5·2 ; 4th 4 weeks, 1:5·2.

GROUP No. 3.—TWO STEERS, NOS. 5 and 6.

Bulky fodder ration No. 2—

Ensilage, 50 lbs................1st 4 weeks, no meal.
Hay, 5 lbs.....................2nd 4 weeks, 2 lbs. meal per day.
Straw, 5 pounds................3rd 4 weeks, 4 lbs. meal per day.
4th 4 weeks, 6 lbs. meal per day.

Nutritive ratio : 1st 4 weeks, 1:12·3 ; 2nd 4 weeks, 1:10·2 ; 3rd 4 weeks, 1:9·1 ; 4th 4 weeks, 1:8·3.

GROUP No. 4.—TWO STEERS, NOS. 7 and 8.

Bulky fodder ration No. 2—

Ensilage, 50 lbs.........1st 4 weeks, no meal.
Hay, 5 lbs...........2nd 4 weeks, 1 lb. meal and 1 lb. oil-cake per day.
Straw, 5 lbs............3rd 4 weeks, 2 lbs. meal and 2 lbs. oil-cake per day,
4th 4 weeks, 4 lbs. meal and 2 lbs. oil-cake per day.

Nutritive ratio : 1st 4 weeks, 1:12·3 ; 2nd 4 weeks, 1:8·2 ; 3rd 4 weeks, 1:6·6 ; 4th 4 weeks, 1:6·4.

GROUP No. 5.—TWO STEERS, NOS. 9 and 10.

Bulky fodder ration No. 1—

Ensilage, 50 lbs...1st 4 weeks, 2 lbs. meal and 2 lbs. bran per day.
Turnips, 25 lbs....2nd 4 weeks, 2 lbs. meal and 2 lbs. bran per day.
Hay, cut, 5 lbs....3rd 4 weeks, 3 lbs. meal and 3 lbs. bran per day.
Straw, cut, 5 lbs..4th 4 weeks, 4 lbs. meal and 4 lbs. bran per day.

Nutritive ratio : 1st and 2nd 4 weeks, 1:7·7 ; 3rd 4 weeks, 1:7·1 ; 4th 4 weeks, 1:6·7.

GROUP NO. 6.—TWO STEERS, NOS. 11 and 12.

Bulky fodder ration No. 1—

Corn ensilage, 50 lbs. 1st 4 weeks, 2 lbs. meal and 2 lbs. bran per day.
Turnips, 25 lbs.,.... 2nd 4 weeks, 1 lb. meal, 1 lb. cotton seed and 2 lbs. bran per day.
Hay, 5 lbs.......... 3rd 4 weeks, $1\frac{1}{2}$ lbs. meal, $1\frac{1}{2}$ lbs. cotton seed and 3 lbs. bran per day.
Straw, 5 lbs......... 4th 4 weeks, 2 lbs. meal, 2 lbs. cotton seed and 4 lbs. bran p. day.

Nutritive ratio: 1st 4 weeks, 1:8·7; 2nd 4 weeks, 1:6·8; 3rd 4 weeks, 1:5·9; 4th 4 weeks, 1:5·3.

GROUP NO. 7.—TWO STEERS, NOS. 13 AND 14.

Bulky fodder ration No 1—

Ensilage, 50 lbs..... 1st 4 weeks, 2 lbs. meal and 2 lbs. bran per day.
Turnips, 25 lbs.... 2nd 4 weeks, 3 lbs. meal and 3 lbs. bran per day.
Hay, cut, 5 lbs.... 3rd 4 weeks, 4 lbs. meal and 4 lbs. bran per day.
Straw, cut, 5 lbs.. 4th 4 weeks, 6 lbs. meal and 4 lbs. bran per day.

Nutritive ratio: 1st 4 weeks, 1:8·7; 2nd 4 weeks, 1:7·9; 3rd 4 weeks, 1:7·3; 4th 4 weeks, 1:7.

GROUP NO. 8.—TWO STEERS, NOS. 15 AND 16.

Bulky fodder ration No. 1—

Ensilage, 50 lbs.... 1st 4 weeks, 2 lbs. meal and 2 lbs. bran per day.
Turnips, 25 lbs.....2nd 4 weeks, 2 lbs. meal 1 lb. cotton seed and 3 lbs. bran per day.
Hay cut, 5 lbs.....3rd 4 weeks, 2 lbs. meal, 2 lbs. cotton seed and 4 lbs. bran per day.
Straw, cut, 5 lbs.....4th 4 weeks, 4 lbs. meal, 2 lbs. cotton seed and 4 lbs. bran per day.

Nutritive ratio: 1st 4 weeks, 1:8·7; 2nd 4 weeks, 1:6·4; 3rd 4 weeks, 1:5·3; 4th 4 weeks, 1:5·3.

GROUP NO. 9.—TWO STEERS, NOS. 17 AND 18.

Bulky fodder ration No. 3—

Timothy hay, 20 lbs...1st 4 weeks, 2 lbs. meal and 1 lb. bran per day.
Turnips, 40 lbs...... 2nd 4 weeks, 1 lb. meal, 1 lb. cotton seed meal and 2 lbs. bran per day.
3rd 4 weeks, $1\frac{1}{2}$ lbs. meal, $1\frac{1}{2}$ lbs. cotton seed meal and 3 lbs. bran per day.
4th 4 weeks, 2 lbs. meal, 2 lbs. cotton seed meal and 4 lbs. bran per day.

Nutritive ratio: 1st 4 weeks, 1:10; 2nd 4 weeks, 1:7·4; 3rd 4 weeks, 1:6·4; 4th 4 weeks, 1:5·8.

GOUP NO. 10.—TWO STEERS, NOS. 19 AND 20.

Bulky fodder ration No. 4—

Brome grass hay, 20 lbs..1st 4 weeks, 2 lbs. meal and 1 lb. bran per day.
Turnips, 40 lbs......... 2nd 4 weeks, 1 lb. meal, 1 lb. cotton seed meal and 2 lbs. bran per day.
3rd 4 weeks, $1\frac{1}{2}$ lbs. meal, $1\frac{1}{2}$ lbs cotton seed meal and 3 lbs. bran per day.
Fed for twelve weeks only.

The Brome grass has so nearly the same nutritive constituents as Timothy that the same figures may be taken: Nutritive ratio 1st 4 weeks, 1:10·; 2nd 4 weeks, 1:7·4; 3rd 4 weeks, 1:6·4.

GROUP No. 11.—TWO STEERS, NOS. 21 AND 22.

Not on test for first half of first 4 weeks.

Bulky fodder ration No. 1.—Ensilage, 50 pounds ; turnips, 25 pounds ; hay, 5 pounds ; straw, 5 pounds.

The last half of first 4 weeks they also received 3 pounds of meal per day, composed of equal parts by weight of pease, barley and oats, all ground. During the remaining 12 weeks each steer received 2 pounds of cornmeal per day, with a gradually increasing quantity of a mixture composed of ¼ ground oil-cake, ¼ cotton seed meal and ½ bran, and a feed of long hay at noon.

Nutritive ratio: 1st 4 weeks, 1:9·8; 2nd 4 weeks, 1:8·2; 3rd 4 weeks, 1:7·2; 4th 4 weeks, 1:6·8.

From the above it will be seen that the best results have been had from the rations fed to groups 1, 2, 4 and 11.

EXPERIMENTS IN THE FATTENING OF SWINE.

Experiments in the fattening of swine have been continued during the past year. These experiments have been conducted at intervals since 1890, using different rations from year to year for the purpose of gaining information regarding the best methods of producing pork of the highest quality and at the least cost. Particulars are submitted as to the different sorts of food used, the quantities consumed and the increase in live weight of the animals under test.

THE FEEDING OF SWINE WITH A MIXTURE OF WHOLE GRAIN, DRY.

Lot 24.—This pen contained four cross-bred swine, two Poland China sire, with Tamworth dam, farrowed 7th April, 1898, one Tamworth sire and Chester White dam, farrowed 1st April, 1898, and one Poland China sire and Yorkshire dam, farrowed 31st March, 1898. These were fed entirely on a mixture of equal parts of unground oats, barley and pease and half a part of bran. The food was all used dry, but the swine had all the water they required in a separate trough ; as much food was given them as they would eat up clean. This feeding test was begun on the 20th July, 1898, and continued for fourteen weeks, or until the 26th of October. The pigs were weighed every two weeks, and the increase in weight and the quantity of food consumed during each four weeks are given in the accompaying tables.

No. of Swine, Four.	20th July.	17th August.	14th September	12th October.	26th October.	Totals.

Nutritive ratio of mixture fed, 1:4·7.

The average live weight of each pig when this feeding test was begun was 67½ pounds; the average weight at the conclusion of the experiment was 175½ pounds.

THE FEEDING OF SWINE WITH A MIXTURE OF WHOLE GRAIN, SOAKED.

Lot 25.—This pen contained four cross-bred swine, two Poland China sire and Tamworth dam, farrowed 7th April, 1898, one Tamworth sire and Chester White dam, farrowed 1st April, 1898, and one Poland China sire and Yorkshire dam, farrowed 31st March, 1898. These were fed for the full period of fourteen weeks on a mixture of equal parts of unground oats, barley and pease, with half a part of bran, all soaked on an average for 30 hours in cold water. They received as much of the mixture as they would eat up clean.

The average live weight of each pig in this group when the test was begun was 66½ pounds; the average weight at the conclusion of the experiment was 190½ pounds.

ON THE FEEDING OF SWINE ON A MIXTURE OF GROUND GRAIN, SOAKED, WITH CLOVER ADDED.

Lot 28.—This pen contained four cross-bred swine, one Poland China sire and Tamworth dam farrowed 7th April, 1898, one Tamworth sire and Chester White dam farrowed 1st April, 1898, one Poland China sire and Yorkshire dam farrowed 31st March, 1898, and one Tamworth farrowed 12th April, 1898. These were fed for the full period of fourteen weeks on a mixture of equal parts of ground oats, barley and pease, with half a part of bran, and cut clover added in sufficient quantity to make a mixture of three parts of meal to one part of clover by weight. The mixed meal and clover was soaked on an average for 30 hours in cold water, and the pigs were given as much of the mixture as they would eat up clean.

Number of Swine, Four.	20th July.	17th August.	14th September	12th October.	26th October.	Totals.
	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.

The average live weight of each pig in this group when the test was begun was 68¼ pounds; the average weight at the conclusion of the experiment was 136¾ pounds.

VISITS TO THE BRANCH EXPERIMENTAL FARMS.

NAPPAN, NOVA SCOTIA.

A visit was paid to the Experimental Farm for the Maritime Provinces at Nappan, N. S., during the second week in July. The various branches of work at this farm were making fair progress, and although seeding had been so very late that crops were necessarily backward, they nevertheless looked healthy and vigorous and promised well.

The stock was found in good order, the dairy herd much improved and the cows giving a good supply of milk, which was proving a great assistance to the Government Dairy Station near by. Some additions to the buildings were needed, and these have since been made. Arrangements were also effected at the time of my visit for a good supply of excellent water from a spring found at the rear end of the farm. A reservoir has since been constructed near the source of the spring and pipes laid to the barn and dwellings, which will supply an abundance of good water which has long been needed.

In the horticultural division of the work the fruit trees had for the most part wintered well, and many of those in the orchards were bearing fruit. A large number of small fruits and vegetables were under test and most of the ornamental trees, shrubs and hedges were making satisfactory progress. The flowers, both perennial and annual were making a very attractive display.

BRANDON, MANITOBA.

The annual journey of inspection westward was made in August. The crops at the Brandon experimental farm, notwithstanding the very dry weather in the spring, were very good. The various sorts of wheat under test there averaged about 30 bushels per acre, barley from 40 to 50 bushels, and many of the varieties of oats being tested in experimental plots exceeded 100 bushels per acre. This farm was in good order, the land had been carefully prepared and the weeds were kept well under. The corn and root crops also promised well, and the yield of potatoes was unusually good.

The forest belts, avenues and ornamental trees and shrubs are all making good progress, and add very much to the attractiveness of the farm and furnish much useful shelter. The stock also was found to be in good condition and satisfactory progress in this branch of the work had been made. Some of the small fruits had given fair crops and quite a number of wild plum trees were found fruiting. The large collection of trees and shrubs and ornamental hedges, which have been planted about the Superintendent's residence, associated with large beds of annual and perennial flowers, now forms a very attractive feature at this farm and receives much attention from visitors.

INDIAN HEAD, N. W. T.

Although this district had suffered much from dry weather in the spring, the copious rains which fell late in June had brought the crops along at a marvellous rate of growth so that by harvest time the fields were as heavy with grain as I had ever seen them. Oats were scarcely so heavy as at Brandon, but the best yielders ran from 70 to 80 bushels per acre. Barley also was a good crop, much like that at Brandon, most of the varieties ranging from 40 to 55 bushels per acre, while the wheat was a heavier yield than at Brandon, many fields giving from 35 to 40 bushels per acre. These good crops have again prevailed over the greater part of that fertile district and in every instance where the land has been well prepared the labours of the husbandman have been amply rewarded.

The large plantations of forest trees, the avenues and wind breaks of various sorts in which there have now been planted over 100,000 trees are making excellent progress, and have made this once bare prairie farm a veritable garden spot on the plains, adding greatly to the beauty of the farm and at the same time affording shelter for buildings, stock and crops.

Continued success attends the experiments with Brome grass, some of the fields at the time of my visit affording excellent pasture. Owing to the very dry spring and the fact of this being a very early grass, the crops both of hay and seed were much lighter than usual. In spite of these drawbacks some of the newer fields did very well. The cultivation of this grass is spreading with great rapidity and it is proving a boon to the settlers everywhere.

The stock, buildings and crops on this farm were all found in good condition and gave evidence of constant and thoughtful care.

AGASSIZ, B.C.

The grain crops at the experimental farm for British Columbia were found to be very fair. Spring wheat ranged from 20 to 25 bushels per acre, oats from 50 to 75 and barley from 30 to 40 bushels. Indian corn has done very well and has given from 20 to 35 tons of well matured fodder per acre, while the crops of field roots and potatoes have been unusually large. The orchards had made very satisfactory growth and many of the younger apple trees were bearing heavily while many older trees were giving light crops. Pears were only a fair crop but included some new sorts of much promise. Plums produced most abundantly and a large quantity was being marketed at the time of my visit. Many of the new sorts were also fruiting. Some very fine varieties of peaches were produced, but the crop of this fruit was light. Many additions have been made to the plantations of small fruits, and also to the number of large fruits under trial.

An additional area of land has been cleared and brought under cultivation. The forest trees, hedges and ornamental trees and shrubs, had all made satisfactory growth, and the general appearance of the farm and the condition of the buildings and stock all indicated careful management.

CHANGES IN THE STAFF.

The only change made during the past year has been the appointment of Mr. W. T. Macoun, formerly the Director's Assistant and Foreman of Forestry, to the position of Horticulturist, occupied until recently by Mr. John Craig.

CORRESPONDENCE.

The following is a summary of the letters received and sent out at the Central Experimental Farm, from 30th November, 1897, to 30th November, 1898, also of the number of reports, bulletins and circulars forwarded by mail during the same period.

—	Letters Received.	Letters Sent.
Director and Acting Agriculturist	49,899	16,425
Horticulturist	690	1,073
Chemist	1,298	1,904
Entomologist and Botanist	2,331	2,506
Poultry Manager	1,583	1,429
Accountant	1,403	1,810
Totals	57,204	25,147

Circular letters sent, including circulars sent with samples of seed grain, 152,351.
Number of reports and bulletins mailed, 214,532.

The volume of correspondence received during the past year has been larger than in any previous year. Much of the increase, however, in letters received by the Director and in circular letters mailed was due to a revision of the mailing list made during the year.

ACKNOWLEDGMENTS.

Grateful acknowledgments are due to the Director of the Royal Gardens, Kew, England, for another useful and valuable collection of seeds of trees, shrubs and plants obtained from different countries. Many packages of the seeds of rare and promising varieties have also been received from the Director of the Arnold Arboretum, Jamaica Plains, Mass. Collections of seeds have also been received from the Agricultural Department of the Government of India. To Prof. John Macoun, Naturalist of the Geological and Natural History Survey, and to Mr. J. M. Macoun, Assistant Naturalist, my hearty thanks are due for seeds of some rare species collected in different parts of the Dominion.

I take pleasure also in acknowledging the continuance of the faithful services rendered by all the officers at the central and branch experimental farms and for their earnest co-operation in carrying on the many lines of experimental work which have been planned.

Special acknowledgments are due to those members of the staff who have rendered me much efficient help in carrying on those branches of the work of which I have had the personal charge. To the Farm Foreman, Mr. John Fixter, who has carefully managed and watched over the field experiments and taken notes on the crops at different stages in their growth. To Mr. Harry Fixter, who has had charge of all the uniform test plots of cereals, also of the small plots of newly introduced varieties, including new cross-bred and hybrid sorts, and has taken records of the growth and yield of all the varieties tested. I am also indebted to him for his careful management of the work in connection with the distribution of samples of seed grain. From Mr. R. R. Elliot, Herdsman, I have also received much valued assistance. He has carefully carried out the work planned in connection with the experiments conducted in the feeding of cattle and swine and has taken notes on the results. Accurate work has also been done by Mr. Wm. Ellis in testing the vitality of seeds, in the propagation of many useful and ornamental plants, and the taking of the meteorological records. The employees also of the farms in every branch of the work have discharged their respective duties faithfully and well.

WM. SAUNDERS,
Director Experimental Farms.

REPORT OF THE HORTICULTURIST.

(W. T. MACOUN.)

DR. WM. SAUNDERS,
Director, Dominion Experimental Farms,
Ottawa.

SIR,—I have the honour to submit for your approval my first annual report as Horticulturist to the Central Experimental Farm. In this report it has been my endeavour to present only such results and features of the work of my department as I consider will be the most valuable to the farmers and fruit growers of Canada, as it is quite impossible in the limited space at my disposal to take up in detail all branches of the work carried on this year.

CHARACTER OF SEASON.

Last winter was not a hard one on trees, shrubs and plants, and the losses and injuries from winter-killing were not great. There was an abundant snowfall, which afforded good protection and prevented the alternate thawing and freezing of the ground, which caused such injury to the fruit trees during the winters of 1895-96 and 1896-97. The spring was an early one, being 10 days earlier than 1897, on the 15th of April ; about 7 days earlier on the 1st of May : and about 7 days earlier on the 1st of June. The frost was out of the ground sufficiently to use the spade on the 12th of April. Nearly all of April was mild, the weather getting cooler, however, towards the close of the month, and on the 19th the temperature went down to 6 degrees below freezing. May and June were warm and little rain fell during those months. There was frost on the 5th and 6th of May, but little injury was done to vegetation. Most of July was dry and hot, but on the 10th the temperature fell to the freezing point in low spots, but did not do any noticeable injury to the fruits and vegetables. August and September were, for the most part, warm and dry, but towards the end of the latter month there were welcome rains, which were much needed, as the season on the whole was very dry. Since that time there has been plenty of rain. The first severe frosts occurred on the 7th and 10th of October, killing the leaves of the grape vines, the cannas, and most of the annuals.

Winter set in on the 26th of November.

FRUIT CROP.

Early apples were a good crop, but some of the winter varieties, though of better size than many of the summer and fall sorts, did not bear heavily this year. There was an abundant crop of both plums and cherries, which were of good quality. Owing to the long, dry, warm fall, the grapes ripened very well this year—130 varieties reaching maturity—and there was an average crop of good fruit. Currants for the most part yielded well, but the English gooseberries were again so badly affected with mildew that there was scarcely any good fruit on the bushes. The American varieties produced good crops, especially the seedlings. A large quantity of gooseberries was destroyed by sunscald this year, owing to the bright, hot weather when they were approaching maturity. This scald was at its worst about the 7th of July. There was only a fair crop of strawberries, owing to the hot weather shortening the season considerably, and the blossoms not being properly fertilized. There were no raspberries of any account, as the plantation is young, but the crop was only fair in this vicinity.

PROGRESS OF THE WORK.

Since my appointment to the position of Horticulturist, in April last, I have tried to master as many details of the work that I was not hitherto familiar with as time would permit, and have continued the work of testing varieties of fruits and vegetables, taking such notes on the same as were likely to be most valuable.

During the summer especial study was made of the Russian apples, of which there are a large number growing in the orchards. It is unfortunate that so much confusion exists in regard to the nomenclature of these fruits, as it is very difficult to determine when a variety is correctly named. The number of names could be reduced considerably with profit, for as many as four synonyms have been found of one variety.

The thorough spraying of the orchards, small fruit plantations and vineyard were also carefully conducted, to prevent the ravages of insect enemies and fungous diseases.

Measurements have again been taken of selected trees in the forest belts, of which the annual growth of the past seven years has been recorded.

Notes were taken, as formerly, on the hardiness, vigour and other characteristics of the trees, shrubs and plants in the Arboretum, and 345 trees and shrubs added to the collection. The labelling of the specimens in the Arboretum has been continued, and more than 500 plants were collected and dried for a herbarium of the Arboretum and Botanic garden.

This autumn, 500 trees, raised from seed of *Pyrus baccata*, hybridized with the larger varieties of apples, were planted in the orchard along its northern boundary. There were also planted at this time 104 shrubs, produced from seed of *Pyrus Maulei* hybridized with *Pyrus japonica*.

All of these hybrids were originated by Dr. C. E. Saunders, or by the Director.

There was also planted along the northern and part of the western boundary, a row of Norway spruce trees for the purpose of forming a wind-break. These trees were planted five feet apart in the row, it being the intention to cut out each alternate one, if deemed necessary, later on. In all, 382 of these trees were planted.

The following is a summary of the approximate number of species and varieties of fruits, vegetables and ornamental trees and shrubs tested at the Experimental Farm this year, which will give some idea of the labour, care and forethought required to carry on the work with accuracy and success :—

Apples	653	Vegetables	1,000
Pears	69	Tobacco	35
Plums	130	Ornamental trees and shrubs	2,700
Cherries	50	Perennial flowers	1,200
Grapes	169	Gooseberries	154
Currants	80	Strawberries	290
Raspberries	128		

Making in all a total of about 6,658 species and varieties under test this year.

The correspondence connected with this division has been considerable, but replies were given as promptly and as satisfactorily as possible. A large number of samples of seedling apples were sent in for examination, the results of which were reported to the sender and opinions given as to their merits.

ACKNOWLEDGMENTS.

To those who have assisted me in naming fruits, identifying diseases of plants, recording the blossoming periods of fruits, and giving me other information sought, I beg to convey my sincere thanks. Among such I would especially mention :—Mr. R. Brodie, St. Henri de Montreal ; Mr. W. H. Dempsey, Trenton, Ont. ; Mr. R. Hamilton, Grenville, Que. ; Mr. R. W. Shepherd, Como, Que. ; Mr. W. W. Dunlop, Outremont, Que. ; Mr. Dearness, London, Ont., and Dr. B. D. Halsted, New Brunswick, N.J., U.S.

My secretary, Mr. J. F. Watson, on account of his familiarity with the records of this division, has been of great assistance to me. I beg also to testify to the zeal of Mr. H. Holz, the foreman of this division, who has endeavoured to keep everything in first class condition and to carry out the work which was planned.

DONATIONS.

The following donations were received during the year, which I beg to acknowledge with thanks :—

Sender.	Donation.
Anderson, J. R., Dept. Agr., Victoria	Roots of *Arctostaphylos media*.
Arnold Arboretum, Boston, U.S.A	Seeds of trees and shrubs.
Buzzell, Miron, Cherry River, Que	Champion of the Earlies potato.
Beach, Prof. S. A., Geneva, N.Y	Seeds of shrubs.
Bergeron, B., Sherbrooke, Que	White Giant, Rose of Erin and Pink Eye potatoes.
Bennett, Maurice, Ottawa, Ont	Scions of Pomme Royale apple.
Black, R. J., Bremen, Ohio	Scions of Wells apple.
Burpee, Atlee, Philadelphia, U.S.A	Seeds of new varieties of flowers and vegetables.
Burpee, Mr., Gibson, N.S	Scions of Mudpig apple.
Botanic Gardens, Belgrade, Servia	Seeds of trees, shrubs and perennials.
Botanic Gardens, Lausanne, Switzerland	79 packages of seeds of perennials.
Bulley, A. K., West Kirby, Cheshire, England	Seeds of perennials.
Craig, Wm., Maritana, Que	Scions of Guerin apple.
Doherty, G. A., Leamington, Ont	Seedling potato.
Darling, J. K., Almonte, Ont	Samples of potatoes and Craig seedling potato.
Faraho, J. P., Wetaskiwin, N.W.T	Seeds of *Prunus domestica besterciensis*
French, G., Melbourne, Australia	Seeds of economic plants.
Gilchrist, A., Toronto, Ont	Plants of Hybrid roses.
Girdwood, Mrs., St. Anne de Bellevue, Que	Roots and cuttings of climbing plants, greenhouse plants.
Graves, W. J., Perry, Ohio, U.S.A	Two trees of Graves peach.
Hamilton, R., Grenville, P.Q	Scions of Amtmann, St. Peter, Flat Aport and seedling apples.
Hobron, Rev. H. F., Yatung, Tibet	115 packages of seeds of trees, shrubs, and perennials.
Hutt, Prof. H. L., Guelph, Ont	Currant cuttings.
Jephson, Mrs. S. Nenagh, Ont	Scions of seedling pear.
Kew, Royal Gardens, England	150 packages of seeds of trees, shrubs and perennial plants.
Lagace, Jules, St. Hilaire, P.Q	Apple scions.
Leef, W. H., Orillia, Ont	Scions of red and yellow seedling plums.
McIntosh, A., Dundela, Ont	Three trees of McIntosh Sweet apple.
Macoun, Prof. J., Geological Survey	Seeds of Western plants.
McCurdy, M., Burlington, U.S.A	Purple potato.
Marsh, H. C., Muncie, Ind., U.S.A	Early Andes, Early Dawn potatoes.
Marsh, J. D., Mille Roches, Ont	Scions of seedling apple.
Meany, E. S., Seattle, Wash., U.S.A	Seeds of Western trees, shrubs, and plants.
Perron, A., St. Hilarion, Que	No. 1 and No. 2 potatoes.
Stephens, C. L., Orillia, Ont	Seedling plum tree.
Spramoter Co., London, Ont	Spray pump.
Whyte, R. B., Ottawa, Ont	Currants, raspberries, perennials.
Washington, Dept. of Agr., U.S.A	Young trees and shrubs; scions and cuttings; seed of Russian cherries.
Yeisley, Chas., Lisbon, Iowa, U.S.A.	Grape scions.

I have the honour to be, Sir,

Your obedient servant,

W. T. MACOUN,

Horticulturist.

HISTORY OF RUSSIAN FRUITS AS GROWN AT THE CENTRAL EXPERIMENTAL FARM, 1888–1898.

As much time as possible was devoted, this season, to the study of the Russian fruits growing on the Farm, for the purpose of determining those varieties which were succeeding best and those which were of the best quality; and also of ascertaining which of the so-called varieties were synonyms. The history of these fruits up to the present time as grown at the Central Experimental Farm has also been worked up as far as possible, partly from the reports of the late horticulturist, partly from other data regarding them, and partly from the trees as they now stand in the orchards. The results of this work are here given.

A large number of Russian fruits have now been tested for ten years at the Central Experimental Farm. In the year 1888 there were planted in the orchards here 133 supposed varieties of apples, 28 of pears, 8 of plums, and 38 of cherries. Since that time, others have been added at intervals, and notwithstanding those which have been winter-killed, there are now about 160 supposed varieties of apples in the orchard, 18 of pears, 28 of cherries, and 7 of plums. A few of the apple trees planted in 1888 fruited in 1890. The trees did well and made vigorous growth up to the year 1892, when blight appeared in the pear orchard and continued to spread throughout that summer and autumn, notwithstanding all efforts to hold it in check. All the Russian varieties of pears were affected, 25 trees being killed to the ground. The apples were also affected that year, though not so seriously. In 1893 the disease appeared earlier in the season and committed great ravages, both among the apples and the pears. Many apple trees were reduced to stubs, while the pears were still more badly injured than in 1892. This left these orchards in a very dilapidated condition. Some trees had died altogether, others were reduced to stumps, and again others, which had large diseased limbs sawn off, had lost their symmetry. The trees were not so much affected in 1894 and 1895, but owing to the severity of the winter of 1895-96 a large number were root killed; the last of the pear trees originally planted going at that time. Further injury from root killing occurred in the winter of 1896-97. During the past two seasons, most of the apples and pears which have been replaced, made good growth, and some of the apple trees which were badly affected by blight are regaining symmetrical proportions. Out of about 288 apple trees planted in 1888, there are now 149 trees living, 139 having died, of which 104 died in the spring of 1896, 27 in the spring of 1897, and 8 this year.

The cherries did well at first, beginning to fruit in 1890. In 1895 a very fine crop was produced, but during the following winter nearly all of the trees were root killed. This was owing, in a large measure, to their being grafted on tender stocks. Since that time they have been propagated to some extent on Bird Cherry (*Prunus pennsylvanica*) stock. Some trees propagated on this stock in 1891 continue to do well. An exception to the almost general winter killing of the cherries in 1895-96, was the Koslov Morello, sent out by the Ontario Fruit Growers' Association in 1890. Out of 24 trees, only 5 died from the effects of that winter. These cherries are, however, on their own roots.

The Russian plums planted in 1888 have all been winter killed with the exception of two trees, Early Red and Voronesh No. 102, and these two trees are not very healthy. Other varieties have been planted of late years, and some of these are doing fairly well.

Russian Fruits, 1898.

Last winter was not a hard one on trees and there were scarcely any losses. Most of the trees in the Russian apple orchard, which were old enough, produced a good crop of fruit this year. Owing to the extremely hot dry weather, the summer apples, to which class nearly all the Russian varieties belong, dropped very badly. The trees on the whole made fair growth, No blight was noticed. About 50 varieties among those planted in 1888 and 1890 look thrifty, but some of these are evidently synonyms, which would reduce this number somewhat.

Of the varieties which fruited this year, the following seem to be the most promising :—

Livland Raspberry (Melonen). There seems to be no difference between these apples as grown at the Experimental Farm from observations made this year. Tree upright, fairly vigorous; fruit medium size, roundish conical; skin pale yellow, well splashed and washed with bright red; flesh white, tinged with pink near skin, firm, crisp, juicy, sub-acid, pleasant flavour; good quality. Ripe 3rd August.

Switzer: The Switzer grown at the Experimental Farm does not colour so highly as that grown by Mr. R. W. Shepherd, of Como, P.Q., fruit of which was examined during the summer. Tree moderately upright, fairly vigorous; fruit medium size, oblate; skin, pale green, almost white, splashed and streaked with bright red; flesh, white, firm, crisp, juicy, sub-acid with a high aroma; good flavour; very good quality. Ripe 10th August.

Pointed Pipka (Summer Arabka, Broad Cheek, Throne, 135 Budd): All the trees, under these names seem to be of the same variety, as fruited this year. Tree spreading, vigorous; fruit above medium size, oblong, conical, ribbed; skin, pale yellow, well splashed and streaked with purplish-red; flesh white, rather coarse, juicy, mild sub-acid, pleasant flavour, good quality.

Romna (Hibernal, Aport, 244 Beadle, Longfield 56 M. —not Longfield as generally grown—, Silken Leaf): These are all apparently the same apple, as fruited at the Experimental Farm this year. Tree vigorous, spreading; fruit above medium size, sometimes large, oblate, conical; skin greenish-yellow, streaked and splashed with purplish-red; flesh yellow, tender, melting, juicy, acid; quality medium. Ripe last week of September. This is more valuable as a cooking apple than as a dessert fruit. It is one of the most vigorous trees that we have.

Plikanoff: Tree planted 1893, vigorous, spreading. Fruited for the first time this year. Fruit large, roundish, slightly conical; skin, yellow, well washed with bright red and splashed with a darker shade; flesh yellowish, tinged with red, rather coarse, fairly juicy, sub-acid, good flavour; good quality. Season probably October.

Repka Winter: Tree upright, fairly vigorous; fruit above medium size, oblate, flattened; skin yellowish-green, lightly streaked and splashed with purplish-red; flesh white, crisp, fairly juicy, mild sub-acid; quality medium. Will probably keep until February.

Antonovka: Though sometimes favourably mentioned, this will, on account of its lack of colour, it being a yellow apple, probably not be a profitable variety.

Winter Arabka: Did not fruit here this year. It is considered one of the best of the Russian varieties, and is a winter apple.

The Switzer and Pointed Pipka are the only two varieties fruiting this year which can compare with dessert apples of their season in the best apple districts of Ontario.

In the year 1890 a Russian seedling orchard was planted, comprising about 3,000 trees grown from seed, imported from E. Goegginger, Riga, Russia. The seed from which these were grown was said to have been taken from apples grown north of Riga. Of these there are now 1,016 remaining, the rest having been killed by blight or winter. These began to fruit last year, and this year about 60 trees bore. None of these apples are sufficiently promising to be worthy of special mention, but a few of them are as good as the majority of the Russian varieties. They will he further tested at Ottawa, and scions sent to the farms at Brandon and Indian-Head to determine whether they are hardy there or not. The rest of the trees which fruited this year will be cut out.

Pears.—The Russian pears, planted since 1895, have done well and have not been much affected by blight since that time. Only one variety, the Baba, fruited in the pear orchard this year, but two others, Gliva Kurskaya, and Sapieganka, which have borne heavy crops annually in the Director's Experimental garden for some years, were again loaded this season. The Russians pears yet tested at Ottawa are in season but a very short period when they get soft and mealy. If used at the proper time, they are fairly good to eat raw and are very nice when preserved, but are not worth planting where other varieties will succeed.

Plums.—The European plums have not done well in the orchard at the Experimental Farm. The situation is very exposed and the trees have suffered severely. This

year, four Russian varieties fruited, namely, White Nicholas, Early Red, Voronesh (blue) and Yellow Voronesh. All of these but Voronesh (blue) are of good quality. The Yellow Voronesh is almost as large as Yellow Egg and of somewhat the same shape, is fairly juicy, sweet, and of good flavour ; cling stone ; good quality. Ripe 22nd August. Two of the hardiest of the European class of plums yet tested here are the Glass Seedling and Richard Trotter.

Cherries.—Of the cherries planted in the orchard from 1888 to 1895, the following varieties have survived : Strauss, Minnesota Ostheim, Ostheim, Cerise d'Ostheim, No. 207, Koslov Morello, Heart-shaped Weichsel, Orel 24, Riga 18, Orel 27, Shadow Amarelle, No. 206, Orel 25, Griotte du Nord, Spate-Amarelle, Brusseler Braun, June Amarelle, Lutovka, Amarelle Hative. Most of the trees of those varieties which were planted in 1888 do not look as if they would live much longer. These trees are on tender stocks. Trees of a number of varieties in a nursery row, propagated on the bird cherry, *Prunus pennsylvanica*, in 1891, are very healthy, and produced a heavy crop of fruit this year, as did also most of the other cherry trees which were old enough to bear. The best of the European and Russian cherries ripened in the following order this year : Amarelle Hative, 26th June. June Amarelle, 2nd July, Shadow Amarelle, 3rd July. Heart-shaped Weichsel, 8th July. Griotte du Nord, 8th July. Orel 25, 8th July. Cerise, d'Ostheim, 12th July, Brusseler Braun, 25th July, Koslov Morello, 26th July. These cherries gave a continuous succession of fruit for about five weeks. The apparent gap between 12th July and 25th July is filled up by the Ostheim, the fruit of which ripened rather unevenly this year.

The Koslov bush Morello cherries, received from the Ontario Fruit Growers' Association in 1890, deserve special mention. These little, bush-like trees, after eight years growth, now average only about 5 feet 6 inches in height.

There are 21 trees yet living out of the original 25 planted. Of these, 15, nearly all of which appear to be different, produced fruit this year. This is the first year that they have fruited to any extent, although planted for eight years. Most of the trees produced fruit of inferior quality, some being bitter, and others very acid. Two of the most promising, on account of their hardiness and lateness in ripening, are the following :—

Koslov Morello (R. 6. T, 29). Tree bushy, height, 5 ft. 7 in. Heavy crop ; fruit large, long, heart-shaped, slightly flattened, firm ; stalk very long, slender ; suture rather indistinct ; skin, deep red ; flesh deep red, juicy, very acid ; pit large, long. Ripe 20th July. Would probably make a good preserving cherry.

Koslov Morello (R. 6. T. 27). Tree bushy, height, 6 ft. 6 in. Fair crop ; fruit large, heart-shaped, rather deep red, firm ; stalk long, stout ; suture, distinct ; flesh bright red, very acid ; pit large, oval, flat. Ripe 26th July.

The observations made this year, and the opinions drawn, are unbiassed, and should another year's experience change my views on the varieties mentioned, I shall be glad to express them.

APPLES.

There are about 653 varieties of apples in the orchards, of which, as already stated, about 160 kinds are Russian. Of this large collection 191 varieties fruited this year. The crop, on the whole, was good, the summer and autumn sorts especially being heavily loaded. Owing to the continued dry weather, the fruit dropped very badly, as was the case in other sections of the country. The fruit of the winter varieties was of good size, but the earlier sorts seemed to be prematurely ripened, and were small, Wealthy, especially, which fruited very heavily, was considerably under-sized. The crop from each tree was measured and a record made of it. This will be done from year to year, in order to learn the productiveness of the different varieties. The trees, for the most part,

made good growth, the leaves being dark green and healthy looking, but in many cases the heart wood of the trees is of an unhealthy colour, indicating that they are not in the condition they should be. This may be due either to the unsuitableness of the climate, to the character of the sub-soil, or some other cause not yet known. Aphides were not troublesome this year. In the spring, before the buds expanded, they were covered with these insects. The trees were sprayed at that time with a mixture of tobacco, water and whale oil soap, made with 10 lbs. of tobacco, 2 lbs. of whale oil soap, and 40 gallons of water. They were sprayed again on the 2nd and 5th of May. The aphides did not occur in sufficient numbers, throughout the summer to cause appreciable injury. The trees received 1 spraying with a copper sulphate solution and 4 with Bordeaux mixture and Paris green. There was scarcely any scab on the fruit, but the Codling Moth, notwithstanding the thorough sprayings the trees received, did considerable injury, especially during late summer. Many of the trees, especially those that are unhealthy, are affected with Oyster-shell Bark-louse, and this is a troublesome insect to fight.

Only 13 trees died during the winter of 1897-98, and these were all injured previously at the roots by winter-killing. On the 25th of July a windstorm uprooted and destroyed 14 trees. All of these also had been previously injured at the roots. The following is a list of most of the standard varieties which appear to be thriving best:

List of standard varieties of apples shriving best.

Baxter.	Malinda.	Salome.
Ben Davis.	McIntosh Red.	Scott's Winter.
Canada Baldwin.	McMahan White.	Stark.
Delaware Red Winter.	Missouri Pippin.	Swayzie Pomme Grise.
Duchess.	North Star.	Tetofsky.
Duke of Connaught.	Patten's Duchess.	Wealthy.
Gano.	Patten's Greening.	Winter Bough.
Gideon.	Pewaukee.	Winter St. Lawrence.
Haas.	Plumb's Cider.	Wolf River.
Lawver.	Red Astrachan.	Yellow Transparent.
Longfield.	St. Lawrence.	

PEARS.

Pears have not been a success in the orchard at the Experimental Farm. From year to year since the first trees were planted, they have been winter-killed or destroyed by blight, so that to-day nearly all the trees in the orchard are comparatively young. None of the trees died last winter, and this year they made good growth and were free from blight. Only four varieties fruited this year, namely, Baba, Coleman's Butter, Longworth, and Flemish Beauty. The Baba is larger than any of the other Russian pears fruited at the Experimental Farm, but is no better in quality. Flemish Beauty seems to be the hardiest variety of the better class of pears yet tested here.

Arrangements have been made to top graft some of the Russian varieties next spring with scions of the better class, in the hope that they will succeed better.

This autumn there were 69 varieties of pears living in the orchard, of which 18 are Russian.

PLUMS.

There are now 130 varieties of plums in the orchard, a large proportion of which have been planted during the past three years, as during the winter of 1895-96 many of the tenderer sorts were root-killed, and these have been replaced by others since that time.

Throughout most of the fruit growing districts of Ontario and Quebec, plums were a heavy crop this year. A plentiful supply of snow prevented root-killing, little injury

was done to the fruit buds, and the flowers seemed to have been well fertilized, so that these three important factors were favourable to the production of a good crop. At the Experimental Farm most of those trees of the American varieties of plums which were old enough were heavily laden with fruit. Our native varieties also produced large crops, and the few European sorts which were in bearing, yielded well.

The aphides, (which were very troublesome), plum blight and curculio were all successfully combated by the use of tobacco water, whale oil soap, Bordeaux mixture and Paris green, prepared in the manner mentioned elsewhere.

The following American varieties were the most promising this year from the standpoint of hardiness, productiveness, vigour of tree, and quality of fruit. They ripened in the order given: Cheney, 26th Aug.; Wolf, 3rd Sept.; Wyant, 9th Sept.; Stoddard, 9th Sept.; DeSoto, 14th Sept.; Van Buren, 26th Sept. Hawkeye which is one of the best of the American plums did not fruit this year. There are a number of other varieties of good quality which began to bear this season, among which are New Ulm, ripe 29th Aug; Ocheeda, ripe 4th Sept.; Comfort, 20th Sept.; Forest Garden, 26th Sept.

CHERRIES.

During the winter of 1895-96 the trees in the cherry orchard were nearly all destroyed by root-killing. This was due partly to the severity of the winter and partly to the fact that the trees were grafted and budded on tender stock. The late horticulturist, since that time, propagated a considerable number of trees on *Prunus pennsylvanica* stock, which has proved very satisfactory here. Those found in the nursery rows were too small to be planted in the orchard last spring, but will be utilized next year. A large number of additional varieties were crown grafted this year, some of which have made 6 feet of growth during the season. There are now 50 varieties in the orchard, of which—were planted this year. Cherries, like plums, were a heavy crop at the Experimental Farm in 1898 on such trees as were old enough to bear.

GRAPES.

There are now 169 varieties of grapes being tested, of which 130 ripened this year. This was a good season for grapes, as the weather was bright and warm during most of September, being very favourable to the ripening of the fruit. The vineyard, which is about 2 acres in extent, is situated on high, light sandy loam soil with a southern exposure. It received a dressing of farm-yard manure last spring, which was ploughed under. It was found that the roots of a considerable number of vines had become exposed by reason of continuous cultivation for the past nine years and on account of the shifting of the soil by the wind, the vineyard being in an exposed situation. It was decided, therefore to discontinue cultivation for this year. After the manure was ploughed under, the ground was harrowed and a strip 5 feet in width seeded down on the 14th of June with Mammoth Red clover and Mammoth Red and Lucerne mixed, at the rate of 12 pounds per acre. The space between this strip and the vines was mulched with strawy manure to prevent the growth of weeds and to conserve the moisture. The clover took well and there is a fine cover crop this autumn. It is proposed to give the vineyard a dressing of wood ashes in the spring, which, with the manure applied this year, should be sufficient fertilizers for some time to come, as it is not deemed advisable to encourage too much growth.

The work of renewing the vines was begun this autumn, as many of the old ones were not very vigorous. This was done by cutting out the old canes and leaving the younger ones to bear the crop.

As, on account of the short season, earliness is one of the chief requisites in varieties of grapes for Eastern Ontario and the province of Quebec, the following table of the

earliest 25 is given to assist planters in making a selection. In this table are given the number of vines of each sort being tested; the date of ripening; colour of the fruit; average yield per vine for several years, and remarks as to quality, etc.

Name.	Number of Vines Tested.	Date of Ripening, 1898	Heaviest Yields per Vine, 1898.		Average Yield per Vine, 1898.		Average Yield per Vine for Five Years.		Colour of Fruit.	Size of Fruit.	Quality of Fruit.

The following varieties of grapes, which ripen later than those mentioned in the above table, have been grown with success at Ottawa, and most of them being of better quality may be planted with advantage, if the locality is favourable:—

Red.—Delaware, Brighton, Lindley, Agawam, and Vergennes. Vergennes, although a late variety, is a good keeper, and should be grown in localities where it will ripen.

White.—Eldorado, Niagara, Duchess. Eldorado sets its fruit badly, but is of very good quality. Niagara, though a good bearer, is very foxey, and on this account is not liked by many.

Black.—Worden, Wilder, Burnet.

CURRANTS.

The currant crop was good this year, and most of the 80 varieties which are being tested, that were old enough to bear a crop, yielded well. Those varieties which were planted recently did not fruit, and of these 16 were planted this year. The plantation of currants is now made up of 44 black varieties, of which 26 are seedlings originated by Dr. Wm. Saunders; 32 red varieties; and 4 white varieties. The seedling black currants, of which special mention was made of the most promising in the report of the horticulturist for 1897, again yielded well this year. Standard, Success, Climax, and Beauty being worthy of special notice. Among the newer red varieties, that known as Greenfield is one of the best. This is a seedling originated by Mr. S. Greenfield, Ottawa East, Ont. For habit of bush, productiveness, and size of fruit it ranks among the best.

In the following table will be found the yields of the different varieties for this season, with other data regarding them :—

RASPBERRIES.

The present raspberry plantation was begun in 1896. Most of the plants were put out in the autumn of that year, but a large proportion of these died. In 1897 little replacing was done, so that the plantation this spring presented a very broken appearance. As many varieties as possible were procured from Canadian nurserymen, but their lists were limited and there was not time to procure many others from Europe, and the San José scale bill prevented importations from the United States, hence this autumn there are yet a large number of blanks to fill. It is expected that a sufficient number of varieties will be procured before next spring to fill the vacant places, but it will be at least two years before uniform and comparative results can be obtained from many of the varieties. There are now in the plantation 75 varieties of red, purple, and yellow raspberries ; 18 of blackcap raspberries ; and 35 of blackberries and dewberries or 128 varieties in all.

STRAWBERRIES.

There are about 290 varieties of strawberries in the plantation which are all being tested under as nearly similar conditions as possible. These wintered well and most of them produced fairly good crops this year. In the Ottawa district a large proportion of the strawberries were more or less deformed and those at the Experimental Farm were not an exception. This was not caused by the bi-sexual and pistillate varieties not being properly intermixed, as those at the Farm were planted with that end in view. The cause was probably due to the hot winds and the unusual dryness of the atmosphere this year, which may have injured the pistils and prevented the proper formation of the berries. The earlier varieties did not seem to suffer so much as the later sorts, although their season was shortened. Preparations have been made for a new plantation of strawberries next spring.

The following twenty-five varieties have given the best returns this year, these being arranged in the order of their yield :—

Variety.	Bisexual. Pistillate.	Date of First Bloom.	Date of First Picking.	Date of Last Picking.	Yield from 1 row 30 ft. long.	Estimated Yield per acre.
	Sex.				Boxes.	Boxes.

The yields of some of the well-known varieties, which do not appear in this list, estimated on the basis of 1 row 30 feet long, were:

Princess	$12\frac{1}{4}$ boxes.	Greenville	$11\frac{2}{3}$ boxes.
Parker Earle	$11\frac{1}{4}$ "	Warfield	$10\frac{3}{4}$ "
Martha	$10\frac{1}{2}$ "	Wm. Belt	$10\frac{1}{4}$ "
Williams	$9\frac{1}{4}$ "	Bubach	$8\frac{1}{2}$ "
Haverland	$8\frac{1}{2}$ "	Marshall	$4\frac{1}{2}$ "

Other varieties which did well on smaller areas, the yields of which are here estimated on the basis of 1 row 30 feet long, are:

Ada	25 boxes.	Bisel	$23\frac{1}{2}$ boxes.
Schuster's Gem	14 "	Saunders	$13\frac{1}{2}$ "
Margaret	14 "	Charlie	$12\frac{1}{2}$ "

GOOSEBERRIES.

In the gooseberry plantation 154 varieties are being tested; of these 105 are European, 6 American named varieties, and 43 seedlings and cross-bred sorts. Nearly all the European varieties were injured to such an extent with mildew that they have proved quite unprofitable here. This is probably due, in part, to the fact that the soil is unsuitable, it being sandy loam and not very moist; as in some gardens in this vicinity where the soil is heavier and more moist gooseberries do not seem to suffer much from mildew. All the varieties were layered this year and a new plantation will probably be made next spring, if the layers are sufficiently rooted, on heaver and moister ground, although there seems to be no soil in the orchard enclosure quite heavy enough for this fruit. The European varieties, which were freest from mildew were Whitesmith, Riccardo, Crown Bob, King of Trumps, Red Humbro, Rifleman, and Slaughterman. Owing to the continued hot weather this year, in July, when the gooseberries were approaching maturity, the fruit suffered badly from sunscald. For two years in succession this has injured the fruit very much in this neighbourhood. Those who allowed the saw fly to eat the leaves off their bushes, lost a larger per cent of fruit than those who sprayed, as the leaves were a protection from the sun. A number of cross-bred and seedling varieties, originated by Dr. Wm Saunders, are quite promising. Some of these are almost as large as the best English varieties, and were free from mildew this year, except in rare instances, grown under the same conditions as the other varieties. The following are descriptions of a few of them:—

Saunders.—Bush, a vigorous grower and a moderate bearer. Fruit very large, nearly round, sometimes slightly oval, brownish red, smooth; pulp sweet, sprightly and of fine flavour. Quality very good. Ripe 22nd July. One of the best of the many seedlings grown here. Free from mildew.

Rideau.—Bush, a strong, vigorous grower and a heavy bearer. Fruit medium to large, round, green, smooth with pale prominent ribs; skin moderately thick, but tender; pulp sweet, sprightly but not high flavoured. Quality good. Ripe 26th July. This is a prolific seedling resembling Downing and Pearl. Fruit almost free from mildew. Rarely a few berries slightly affected.

Gibb.—Bush, a strong grower and a medium bearer. Fruit large, oval, sometimes oblong; skin green with an amber tint, smooth; pulp sprightly and of good flavour. Quality good. Ripe 27th July. The amber colour of this seedling makes it easily distinguishable from other varieties. Fruit almost free from mildew; a few berries very slightly affected.

Ruth.—Bush, a strong grower and a very heavy bearer. Fruit medium size, oblong, sometimes oval; skin green, smooth, moderately thick but tender; pulp sprightly, sweet but not high flavoured. Quality good. Fruit nearly, free from mildew; a few berries, only, being slightly affected.

Seedling Gooseberry—Saunders, about two-thirds natural size.

FUNGOUS DISEASES.

Owing to the large amount of other work to be done in connection with this department, not much time has been devoted to this branch of the work. The spraying for the prevention of fungous diseases was, for the most part, such as has been recommended by the late horticulturist, but it is hoped that next year more experiments will be conducted and new experience gained.

A considerable number of samples of diseased fruit, bark, branches, and leaves were received for identification and for information as to remedies. As far as possible, and with the help of experts, satisfactory replies were given.

The species of dry rot of the apple of which mention was made in the reports of the Horticulturist for 1896 and 1897, was again troublesome this year. Red Astrachan, Shiawassee Beauty, Fameuse, Borovinka and Romna were affected. Fameuse was the least affected, but nearly all the fruit of Red Astrachan was spoiled, almost all of one tree of Romna, and the greater part of one tree of Shiawassee Beauty. Most of these trees are too far distant apart to be affected one from the other. This disease is not confined to Eastern Canada, as specimens of fruit affected with it have been received from British Columbia. The cause and life history of this disease is being investigated by Dr. Connell, of Queen's University, Kingston. Samples of diseased fruit were sent to him in 1897, and again this autumn. Under date of 2nd Dec., 1898, he gives the results of his investigations up to that time, which are as follows:—

"In two of the Shiawassee Beauty apples received this autumn I obtained micro-organisms from a single rot 'spot' in each. In all other apples and in remaining 'spots' of these two I could detect no micro-organisms. The organisms obtained in the spots differed from each other; one being a white micro-coccus, the other a yellow bacillus. Evidently both are present in the role of invaders, not as causal agents.

"To sum up roughly my work so far in connection with the dry rot spot. In the first samples sent me early in 1897, I found almost constantly present a fungus resembling *Gloeosporium fructigenum*. Later, however, in other samples obtained from other localities this form was absent, and when I got any micro-organisms at all they were of different species—other fungi, yeasts, sarcinæ, micrococci, and bacilli. All these, to my mind, have no causal relationship to the trouble, and when present they are like those in my recent samples, almost certainly secondary. If the cause be micro-organismal—which I much doubt—then certainly I have so far failed to find any constant form present. Puncture of insects or some nutritional cause are the other factors to be considered."

SPRAYING.

The spraying of the different fruits, ornamental trees, shrubs and flowers was carried on from early spring until it was thought to be no longer necessary, the good results of which were very apparent on nearly everything so treated.

Apples and Pears.—The apple and pear trees were sprayed 8 times, the first spraying being with a sulphate of copper solution on 22nd April, one pound of sulphate of copper to 25 gallons of water. They were sprayed on 13th and 31st May, 16th June and 6th July, with Bordeaux mixture and Paris green, the formula of 4 pounds lime, 4 pounds sulphate of copper, and 40 gallons of water being used. On 23rd April, 2nd May, and 5th May, the trees were sprayed with tobacco water and whale oil soap, made by soaking 10 pounds of waste tobacco in 40 gallons of water and adding two pounds of whale oil soap.

Plums.—The plum trees were sprayed nine times: with Bordeaux mixture and Paris green on 27th May, 7th June, 16th June, and 5th July; with tobacco water on 26th April, 6th May, 28th May, 31st May and 6th July.

Cherries.—The cherry trees were sprayed twice: once with tobacco water and whale oil soap, on 26th April; once with Bordeaux mixture, on 27th May. One more spraying with Bordeaux mixture and one with ammoniacal copper carbonate are recommended, but were omitted this year.

Grapes.—The grape vines were sprayed five times: once with the sulphate of copper solution and Paris green, on 2nd May; and with Bordeaux mixture and Paris green, on 27th May, 16th June, 4th July and 23rd July.

Gooseberries.—The gooseberries were sprayed with Bordeaux mixture and Paris green three times, namely, on 10th May, 30th May and 9th June.

Besides the above, certain ornamental trees and shrubs and flowering plants, affected with different diseases and insect pests, were sprayed when it was deemed necessary. The Larch trees, for instance, were sprayed with Paris green to kill the saw-fly; the roses were sprayed with Paris green and tobacco water; the snowballs were sprayed with tobacco water to kill the Aphides. The dogwoods were sprayed with kerosene and water to kill the oyster-shell bark-louse, and the irises were sprayed with Bordeaux mixture to prevent disease. Owing to the depradations of the forest tent caterpillar in this district, there were more people than usual inquiring about spray pumps, and after seeing those in operation at the Experimental Farm they went away with the determination to purchase one.

COVER CROPS.

The clover sown for cover crops on 1st August, 1897, in the orchards, mention of which is made in the report of the Horticulturist for that year, came through the winter in splendid condition. Nowhere was there any winter-killing and when growth began it was a fine sight to behold. On the 13th June clover in the crab apple, pear, and plum orchard was turned under. Part of this land was re-seeded on the 14th July, with Mammoth Red clover, at the rate of 12 pounds per acre, and part with about equal parts of Mammoth Red clover and Lucerne mixed. This formed a good covering by autumn. In a part of the apple orchard where the soil is very poor, the clover was ploughed under on the 26th May. The land was harrowed and pease were sown at the rate of 2½ bushels to the acre on 1st of June. On the 22nd July, when the pease were beginning to bloom, and about 2 feet 6 in. high, they were turned under, and, after harrowing, equal parts of Mammoth Red and Lucerne clovers were sown at the rate of 12 pounds to the acre. Owing to the very dry autumn, the Mammoth Red clover did not make as vigorous a growth as could be desired, but the Lucerne was 11 inches in height when frozen. These two crops of leguminous plants ploughed under this season will improve the texture of the soil and enrich it considerably. The clover in the greater part of the apple orchards was not ploughed under this year. This is contrary to what is usually recommended, but it was left for several reasons. In the first place, the soil in the orchard is a sandy loam which is easily moved by the wind. During the years in which the orchards have been under cultivation, the soil has blown away so much from a number of the trees that the roots are more or less exposed. A second reason why it was left, was to determine whether the trees would seem to suffer in time of drought. Notwithstanding the exceptionally dry summer which we had, neither the clover nor the trees seemed affected by drought, except in a small portion of the Russian orchard. This would seem to indicate that the soil in the orchards does not lack moisture. Taking all things into consideration, namely, the texture of the soil, its capacity for holding moisture, the exposure of the orchard, the destruction of purslane, which it seems impossible otherwise to kill, even with thorough cultivation, and the belief that it is better not to encourage too vigorous growth when so near the limit of the successful growing of large fruits, it was thought better not to cultivate this year.

SEEDLING FRUITS.

Besides the fruits sent in for name this year, a number of seedling apples, pears and plums were received for examination. Most of the varieties sent, were not of sufficient value to recommend their being propagated to any extent. A few, however, were promising, and these are described below. The descriptions here given may require modifications in future, as in some cases only one sample of the fruit was received, which may not have been a typical specimen.

It is hoped that correspondents will continue to send samples of fruit in the future, which will be carefully tested and the results of observations made, given to the sender. As there is a special committee of the Ontario Fruit Growers' Association, of which the writer is a member, whose work it is to report on new fruits, brought under their notice, it is desirable that at least four—and if possible, eight—samples of the fruit be sent from persons living in that province, in order that they may be submitted to the four men, who comprise this committee, as in this way the opinions of four, instead of one, would be had of the fruit, and fairer conclusions could be drawn.

Record No. 153. Apple seedling. Tested 19th October, 1898. From J. S. McCallum, M.D., Smith's Falls, Ont.

Description.—Above medium, oblate ; skin yellow, splashed and washed with dull red ; dots numerous, prominent, yellow. Cavity narrow, moderately deep ; stalk short, stout ; basin narrow, moderately deep, smooth ; calyx open. Flesh yellowish, juicy, subacid with a pleasant, sprightly flavour. Core small. Said to keep until April. Quality, good. Supposed to be a seedling of Baxter. Scions received, 1897.

Record No. 163. Apple seedling. Tested 16th November, 1898. From J. D. Marsh, Mille Roches, Ont.

Description.—Above medium size, conical, prominently ribbed towards basin. Skin green, splashed and washed with purplish red; cavity deep, moderately wide; stalk short, slender; basin narrow, shallow, wrinkled; calyx closed. Flesh greenish-white, juicy, brisk sub-acid, pleasant flavour, not unlike that of Rhode Island Greening. Core, medium size. Quality good. Season, late winter. Tree said to be fourteen years old and very hardy. Scions asked for.

Record No. 168. Guerin apple. Tested 14th October, 1898. From Wm. Craig, Maritana, Que.

Description.—Large, roundish. Skin greenish-yellow, washed and splashed with deep purplish-red; dots fairly numerous, white, distinct on sunny side. Stalk short, fairly stout; cavity medium depth and width; basin narrow, round, smooth, shallow; flesh white, fine grained, fairly juicy, mild sub-acid. Quality above medium. Season probably October. Said to have originated on the Indian reserves of Caughnawaga.

Record No. 149. Apple seedling. Tested 14th October, 1898, from Robert Hamilton, Grenville, Que.

Description.—Medium size; skin pale yellow, almost entirely covered with deep red; dots few, gray, obscure; cavity deep, open; stalk long, slender; basin of medium width and depth, almost smooth; calyx open; flesh white, tinged with red in places, fine grained, fairly juicy, mild sub-acid; flavour slightly resembles McIntosh Red; core, small. Quality good. Season probably September and October. Scions asked for.

Record No. 154. Seedling apple. Tested 9th November, 1898. From S. Greenfield, Ottawa East.

Description.—Large, roundish, slightly conical; skin pale yellow, splashed and washed with bright red, mostly on sunny side; dots fairly numerous, gray, rather prominent on shady side; cavity narrow, moderately deep; stalk short, stout; basin of medium width and depth, slightly wrinkled; calyx partly open: flesh yellow, juicy, acid; core large. Quality above medium.

Record No. 169. Pear seedling. Tested 9th November, 1898. From Mrs. S. Jephson, Nenagh, Ontario.

Description.—Medium size, obtuse pyriform, surface irregular, with small protuberances; skin green, with a pink blush; cavity shallow; stalk three-quarters of an inch long; basin moderately deep and open, smooth; calyx open. Flesh pale yellow, juicy, sweet, rich, high flavoured; core small. Quality good. Season probably late October and early November. Tree said to be 11 years old and has been fruiting for two years. Scions asked for.

Record No. 173. Emerald plum. Tested 4th August, 1898. From E. D. Smith, Winona, Ont.

Description.—Above medium size, oval; skin yellow; suture distinct; cavity narrow; stalk short, stout; flesh yellow, juicy, sweet, rich, good flavor; freestone. Quality good. Said to bear annually and ripens in July. Scions asked for.

Record No. 176. Seedling plum. Tested 24th September, 1898. From F. R. Latchford, Ottawa.

Description.—Large, oval, deep purple with a blue bloom; suture obscure; cavity narrow, shallow; stalk three-quarters of an inch long; flesh greenish-yellow, juicy, sweet; pit of medium size, oval, clingstone. Quality good. A promising late plum. Tree said to be about 50 years old, producing a full crop every three years, when it bears very heavily. Scions asked for.

Record No. 172. Seedling plum. Tested 21st September, 1898. From S. Greenfield, Ottawa East.

Description.—Large, roundish, almost oval; skin purplish-red with a slight purple bloom; suture distinct, shallow; cavity shallow, of medium width; flesh greenish-yellow, juicy, sweet, rich; pit, large, clingstone. Quality good. Scions asked for.

LIST OF BEST VEGETABLES FOR FARMERS.

When the farmer begins to think of getting his garden seeds, he is often puzzled as to just what to select from the large list of varieties offered for sale by seedsmen. Often, also, he is mislead by the glowing descriptions given by the seed dealers, and purchases varieties which are not satisfactory to him. Still more frequently, however, he has no seed catalogue to guide him, and he simply purchases from a local firm whatever is offered to him. The following list is given of those vegetables which have proved the best and most satisfactory at the Central Experimental Farm, with the hope that it will prove useful to the farmers of Canada in the selection of their garden seeds. In making this list, the quality, yield and time when they are fit for use have been taken into consideration. Quality being considered the most important:—

Asparagus.—Seven varieties are being tested. Connover's Colossal is the best all round variety.

Beans.—Seventy-four varieties were grown this year. Golden Wax or Wardwell's Kidney Wax, for early crop; Early Refugee, for medium; and Refugee or 1,000 to 1, for late crop, are the most satisfactory dwarf varieties. Southern Crease-back and Asparagus, (early) and Golden Andalusia, (late), are the best pole varieties.

Beets.—Thirty-two varieties tested. Egyptian Turnip, Eclipse, and Bastian's Blood Turnip are three of the best varieties.

Borecole or Kale.—Four varieties tested. Dwarf Green Curled Scotch is the best.

Broccoli.—One variety tested; White Cape which is good.

Brussels Sprouts.—Four varieties tested; Improved Dwarf proved the most satisfactory.

Cabbage.—Fifty-two varieties tested. Early Jersey Wakefield (early, Succession (medium); Late Flat Dutch, Drumhead Savoy, (late); Red Dutch, (red), is a select list of the best varieties of cabbage.

Cauliflowers.—Thirty-one varieties tested.—Extra Early Dwarf Erfurt and Early Snowball, (early); Kronk's Perfection, (medium) and Large Late Algiers are among the best.

Carrots.—Sixteen varieties tested. Chantenay and Guerande or Oxheart are two of the best carrots, but if a good extra early sort is required the Early Scarlet Horn can be planted with advantage. It is a small variety.

Celery.—Twenty-nine varieties tested. Golden Self-Blanching, Paris Golden Yellow, Improved White Plume, (early); London Red, White Triumph, (late), are among the best.

Corn.—Thirty-six varieties tested. Early White Cory, Crosby's Early, Henderson's Metropolitan, (early); Perry's Hybrid, Stabler's Early, (medium); Stowell's Evergreen, Country Gentleman, (late.) In planting, the Country Gentleman should not be omitted, as it lenghtens the season very considerably, and is of fine quality.

Cucumbers.—Thirty-three varieties tested. Peerless White Spine or White Spine, Cool and Crisp, and Giant Pera are three of the most satisfactory slicing varieties. Boston Pickling is a good pickling sort.

Egg Plants.—Six varieties tested. New York Improved and Long Purple succeed best.

Lettuce.—Twenty-nine varieties tested. Black Seeded Simpson, New York, (curled); Tennis Ball, Salamander, and Golden Queen, (cabbage); Trianon and Paris White Cos lettuce make a good list.

Melons, Musk.—Nineteen varieties tested. Long Island Beauty, Hackensack and Montreal Market, of the Nutmeg type, and Surprise, Bayview and Christiana, of the other types, are all good.

Melons, Water.—Ten varieties tested. New Imperial, Ice Cream, and Phinney's Early, are water melons of excellent quality.

Onions.—Fifty-five varieties tested. Yellow Globe Danvers, and Large Red Wethersfield, are two of the best onions in cultivation.

Parsnips.—Three varieties tested. Hollow Crown and Dobbies Selected are both good sorts.

Parsley.—Eight varieties tested. Double Curled is as good as any.

Peppers.—Fourteen varieties tested. Cayenne, Cardinal, Squash, and Golden Dawn are four of the best.

Pease.—103 varieties tested. Nott's Excelsior, American Wonder, Gradus and Gregory's Surprise, (early); Heroine, Improved Stratagem, and McLean's Advancer, (medium). None of these are tall growing varieties. Juno (dwarf), Telephone, Veitch's Perfection (tall), (late).

Potatoes.—Extra Early: Earliest of all and Burpee's Extra Early (pink and white). Early: Everett and Rochester Rose, (pink), Early Puritan, (white). Medium: Carman No. 1, (white), Empire State, (white). Late: Late Puritan, (white), American Wonder (white), Rural Blush, (pink).

Radishes.—Forty-two varieties tested. Early: Rosy Gem, French Breakfast, Red Rocket. Late: White Strasburg, Long White Vienna. Winter: Long Black Spanish, Chinese Rose-coloured.

Rhubarb.—Six varieties are being tested. Linnæus and Victoria are the most satisfactory.

Salsify.—Four varieties tested. Long White is the best.

Spinach.—Eight varieties tested. Victoria and Thick-leaved are the best.

Squash.—Twenty-four varieties tested. Early: White Bush Scalloped and Summer Crook Neck. Late: Hubbard.

Tomatoes.—One hundred and three varieties tested. Early:—Earliest of All, Dwarf Champion, and Early Ruby. Main crop:—Brinton's Best, Livingston's Favorite Matchless, and Baltimore Prize Taker.

There are many varieties of this vegetable which are almost equal in excellence and productiveness.

Turnips.—Twenty-four varieties tested. Early:—Extra Early Milan and Red Top Strap Leaf. Swedes:—Champion Purple Top, Skirving Improved.

EXPERIMENTS WITH POTATOES.

This year was not very favourable for potatoes, as the weather was dry throughout most of their growing season and the yield on that account was not so large as usual. In a test of 116 varieties, however, grown under as nearly uniform conditions as possible, the average yield per acre of the whole series was 253 bushels 19 pounds, which is 170 bushels 59 pounds above the average for Ontario for this year, and 138 bushels 19 pounds above the average for the past 17 years. The average of the best twelve was 243 bushels 21 pounds above the average for Ontario, and of the poorest twelve 61 bushels 34 pounds above. The average for Ontario, for 1898, was 84 bushels. This would seem to indicate that the farmers throughout the country are not adopting the best methods of cultivation, or are not growing the most productive varieties. The potatoes were planted this year in the orchard enclosure in sandy loam soil, which was in good condition. This land was ploughed in the autumn of 1897, and again in the spring of 1898, shortly before the time of planting; then disc-harrowed, and finally brought into condition for planting, by the smoothing harrow. The drills were made about 6 inches deep and 2½ feet apart, and the sets, which had, as a rule, three eyes, were of good size and were dropped 1 foot apart, each variety occupying one row 66 feet long. The potatoes were covered with the hand-hoe to insure the most uniform conditions. Just as the vines were coming through the ground, the land was harrowed to kill weeds. The potatoes were cultivated three times throughout the summer, but were not hilled up. They were sprayed once with Paris green alone and five times with Bordeaux mixture and Paris green mixed. The potatoes were planted on May 26th and 27th, and dug on the 6th and 7th October.

Besides the uniform test plots, experiments were conducted to determine the best time of planting, the best depth to plant, the best distance apart in the rows to plant and how the seed should be cut to produce the best crops. Results of tests of this kind vary so much, however, from year to year, and with different varieties, that several seasons trials are necessary before satisfactory data can be obtained.

Every year samples of potatoes are received for test, which are either seedlings not yet named, new named varieties, or varieties for identification. As the quantity received of each of these is usually smaller than that used in the uniform test plots, the comparison of yields between these and the named varieties would not be very conclusive. For this reason, the results of the samples received this year are put in a separate table. Those varieties, also, not yet named which we have had for more than one year, are not included in the uniform test plots, and another table shows the results obtained from them.

TOMATOES.

There were 103 varieties of tomatoes under test this year, the experiments conducted being to determine the productiveness, earliness and freedom from rot of the different sorts. These were grown under as nearly uniform conditions as possible, so that the results might be more reliable. The seed was sown in hot-beds on the 11th of April; the plants transplanted into strawberry boxes and put into cold frames on the 3rd of May; and transplanted to the field on the 3rd of June. Six plants of each variety were used in the uniform test plots and were planted 4 x 4 feet apart. The early part of the season was dry, and during this period the yield was light, but later on there was a good crop and the total yield was large. In the following table particulars are given regarding the different varieties tested:—

Order of Merit.	Variety.	Date of first Ripe Fruit.		Yield of Ripe Fruit from first three pickings.		Yield of Ripe Fruit from last three pickings.		Total Yield of Ripe Fruit.		Yield per Acre of Ripe Fruit.		Yield per Acre of Green Fruit.		Yield per Acre of Rotten Fruit.

GARDEN PEASE.

There were 103 varieties of garden pease tested this year, but as a list of 101 varieties was given in the report of the Horticulturist for 1896, with information regarding them, a full list is not published this year. In the following table, however, will be found a list of the earliest 25 varieties tested, with notes as to time of blooming, time when ready for table use, productiveness, quality, etc. The pease were planted on 13th April, in rows 15 feet long, 200 pease of each sort being used. A list of the best varieties covering the whole season will be found in the "List of Best Vegetables for farmers," which appears on page 109 of this report.

TWENTY-FIVE EARLIEST VARIETIES OF PEASE.

Name.	Seedsmen.	Date of Blossoming.	When Ready for Table.	Average number of pease per pod.	Yield of dried pease. Lbs. oz.	Kind of pease, wrinkled or smooth.	Height. Feet.	Quality.

American Wonder....	Thorburn.	" 30...	" 17...	6	1 3½	W.	1 to 1½..	Very good.
Alaska....................	" .	" 30...	" 17...	5	1 7	S.	2 to 2½..	Good.
Extra Early....	Landreth.	" 30...	" 17...	5	1 11	S.	1 to 1½..	"
Evergreen Pod	" ..	" 30...	" 17...	6	.. 8	W.	2 to 3...	"
New Maud S....	Buckbee..	" 30...	" 17...	5	2 7	S.	4 to 4½..	Medium.
Philadelphia..	Thorburn.	" 31...	" 17...	5	1 11	S.	4 to 4½..	"
Gradus (Prosperity)..	Dreer	" 29...	" 18...	7	.. 12	W.	2 to 3½..	Very good.
Alpha....................	Thorburn.	" 29...	" 18...	5	1 ½	W.	4 to 4½..	Good.

NOTE.—Exonian, Gregory's Surprise, Evergreen Pod and Gradus did not germinate well, which accounts, in part, for the small yield of these varieties. Nott's Excelsior, which was ready for use on June 20th, and is one of the best early pease, is deserving of special mention.

TOBACCO.

The testing of different varieties of tobacco was continued this year, 35 sorts being planted. The seed was sown in a hot-bed on the 16th April ; the young plants transplanted into a cold frame on 30th May, and most of them planted in the field on the 13th June.

The tobacco was grown on a sandy loam soil, enriched with a heavy dressing of farm-yard manure and a crop of Lucerne clover, which was ploughed under on the 20th of May. The land was then disc-harrowed. Previous to planting it was disc-harrowed again, and brought into good condition with the smoothing harrow. The tobacco was planted in rows 4 feet apart and 3 feet apart in the rows. Fifteen plants of each variety were set out in uniform test plots, while larger plots were also planted of some

sorts. The soil was cultivated at intervals (four times in all) to kill weeds and preserve moisture, until the plants were too large to admit of the passage of a horse between the rows without injury to the leaves. As the different varieties were not in the same condition at one time, the topping and priming of all could not be done on the same days. The tobacco made very satisfactory growth, and most of the varieties matured sufficiently to be in good condition for cutting on the 9th September, when the plants were cut and taken to the curing house, where, after they were cured, the leaves were stripped off, weighed, and piled for fermentation.

In the following table particulars are given of the date of topping, total weight of first grade dried leaves, weight of second grade dried leaves, weight of third grade dried leaves and estimated total weight per acre of dried leaves :—

Name.	Seedsman.	Date of Topping.	Yield per acre dry leaves, 1st grade.		Yield per acre, dry leaves, 2nd grade.		Yield per acre, dry leaves, 3rd grade.		Total yield per acre dry leaves.

The Kentucky Burley, White Burley, Yellow Pryor, Yellow Mammoth, Connecticut Seed Leaf, and Pennsylvania Seed Leaf are, taking everything into consideration, probably the most profitable varieties to grow. Some of those which yielded heavier than these were too late in maturing to reach the best condition.

FOREST BELTS.

The work of taking measurements of the growth of the trees in the forest belts has been continued this year. The trees, on the whole, have not made very strong growth, but the white, Scotch, and Austrian pines and European larch have done well. The white pine, especially, which, in some places, is growing on apparently almost pure sand, continues to make a growth of from 2 to 3 feet each year.

Cultivation was continued in those parts of the belts where the trees do not make sufficient shade to prevent the formation of sod or the growth of weeds. The belt planted in the autum of 1894 was cultivated during part of the season, but the trees in the greater part of this belt will not require cultivation in future. Tamarac and canoe and yellow birch, which were pulled up in an adjoining swamp with very few roots, and planted in this belt, have become well established and made good growth this year.

In the mixed forest belt, where the different varieties are intermingled, some of the faster growing trees had begun to exclude the light from those which had not made such rapid growth. A man with a hook was sent through the belt and the obstructing branches cut back, so as to allow the full rays of the sun to reach the leaders of the over-shadowed trees. This, in many cases, saved the pine trees, and in other cases preserved their leaders from destruction. It will be necessary to continue this work from year to year, in order to save the more valuable timber trees and to assist in the formation of tall, straight trunks.

The Russian poplars continued to die from the species of dry rot mentioned in previous reports. The variety known as *Populus alba bolleana*, which makes such a handsome tree, has, during the past two years, become badly affected, and numbers of them have died and are still dying. Each year's experience demonstrates that black walnut will not succeed where there is a cold, wet subsoil. The trees in the forest belts where the soil is of this character are almost at a standstill, while in other places on the farm where they are in warmer soil, they make a growth of from 2 to 4 feet in a season. The black walnut trees planted in 1888 in clay loam soil began to fruit last year, and again had some nuts this year, but the boys got them before they reached maturity.

In order to give some idea of the height and circumference which a few of the best known timber trees reach in a few years when planted on suitable soil, the following figures are given, but for exact measurements and fuller details the reader is referred to my report, as Foreman of Forestry, for 1897.

Name.	When Planted.	Height or Age when Planted.	Approximate Height, 1898.	Circumference, One Foot from Ground, 1898.
			Ft.	Inches.
White Pine—*Pinus Strobus*	1889	8 to 10 inches	18	11½
Scotch Pine—*Pinus sylvestris*	1888	18 inches ...	20	13
Austrian Pine—*Pinus austriaca*	1889	18 " ...	14	13
White Spruce—*Picea alba*	1889	15 " ...	11	8
Norway Spruce—*Picea excelsa*	1888	15 " ...	18	12¼
White Ash—*Fraxinus americana*	1889	3 years	22	8¾
European Larch—*Larix Europæa*	1888	2 feet ...	23	14
Black Walnut—*Juglans nigra*	1888	1 year	14	9
Canoe Birch—*Betula papyracea*	1889	3 feet	27	11
Yellow Birch—*Betula lutea*	1889	3 "	19	10½

ARBORETUM.

The collection of trees, shrubs and perennials has been considerably augmented this year. Of trees and shrubs 314 species and varieties have been added, and of perennials 285 species. There were living in the Arboretum this autumn about 2,700 species and varieties of trees and shrubs, and about 1,200 species and varieties of perennials. This collection, which has been gradually brought together, contains many rare and beautiful species, some of them of peculiar interest to the botanist, and others to the lover of ornamental trees, shrubs and flowers.

PROGRESS OF THE WORK.

During the summer, notes were taken on the hardiness, dates of blooming, and growth of the different species and varieties. A herbarium of the plants growing in the Arboretum is being made, for which 535 specimens were dried and will be mounted this winter. The work of labelling the additions to the Arboretum was also carried on. Last winter an alphabetical list was prepared of all the trees and shrubs growing in the Arboretum, with notes on the hardiness and date of planting of the different species and varieties. It is hoped that this list will shortly be published. There was little increase in the amount of hand labour required to keep the Arboretum in order, the bulk of the work being the cutting of the grass, which is done by the pony lawn mower, and the season being dry it was not cut so often, as it otherwise would have been. A new one-horse field mower was procured this year, which proved very valuable on side hills, and when the grass became too long to be cut well with the pony mower. An additional three acres were seeded down during the summer, on most of which was a good catch of grass this autumn.

ADDITIONAL LIST OF CHOICE HARDY PERENNIALS.

In my report for 1897, a list of 100 of the best hardy perennials was given, with short descriptions of them. There are so many beautiful flowers and so many new ones appearing from time to time, that a few additions to that list are here given, in the hope that it will help others in the selection of choice perennials for their gardens. One correction should be made in the list published last year. The plant at the Experimental Farm which was supposed to be *Campanula Grossekii* is not that species. The true *Grossekii* does not deserve a place in the list of 100 of the best varieties.

Aethionema coridifolia.—Mount Lebanon Candytuft (Orient) : This is a charming little plant about six inches in height. It begins to bloom in the third week of May, and stays in flower from four to six weeks. Flowers, small, bright pinkish lilac, borne profusely in heads. Leaves, narrow and glaucous.

Ajuga genevensis.—Geneva Bugle (Switzerland) : Height, four to six inches. Begins to bloom in the last week of May. The flowers of this pretty dwarf perennial are bright blue, and being a profuse bloomer it presents, when in full bloom, a very attractive appearance.

Asclepias incarnata.—Flesh-coloured Milkweed (Canada) : Height, three to four feet. In bloom, July and August. Flowers, bright purplish red. This fine native wild flower accommodates itself well to the perennial border, and in large collections it should not be omitted.

Helenium grandicephalum striatum.—Large Striped Sneezewort. United States. Height, 3 to 4 feet. In bloom August, September and part of October. Flowers, deep yellow, streaked with brown. This is a very striking and unique looking plant, blooming over a long period.

Campanula latifolia macrantha.—Large Flowered Bell-flower (Europe). Height, 3 to 4 feet. In bloom first week of July. Flowers, large, deep blue, borne on a long spike. A very handsome variety.

Echinacea purpurea.—Purple Cone Flower (United States). Height, 2 to 3 feet. In bloom August and September. Flowers, large, deep reddish-purple, borne singly on long stems. A very fine autumn flower.

Epimedium pinnatum (sulfurum).—Yellow Flowered Barrenwort (Persia). Height, 8 to 12 inches. In bloom second week in May. Flowers, bright yellow, borne in a loose panicle. This species and *E. rubrum* make a charming contrast when planted together. It is one of the most dainty early flowering perennials yet tested.

Group of Arbor-vitae in the Arboretum at the Central Experimental Farm, Ottawa, Ontario.

Group of Pines and Spruces in the Arboretum at the Central Experimental Farm, Ottawa, Ontario.

Heliopsis pitcheriana.—Pitcher's Ox-eye (United States). Height, 3 to 4 feet. Blooms during July, August and September. Flowers, large, deep yellow and very abundant. This is a fine late summer and autumn flowering perennial; its time of bloom covering a long period.

Iris aurea.—Golden Iris: (Himalayas). Height, 3 to 4 feet. In bloom during the first week of July. Flowers, large, deep yellow. One of the most beautiful of all irises. Its lovely colour, stately appearance, and its lateness in blooming make it very desirable.

Iris pallida.—Pale Iris. (South Europe). Height, 2 feet. In bloom, first week of June. Flowers, lilac purple and bright purple. This is a very delicately tinted iris, of which there are some fine varieties.

Polemonium humile pulchellum.—Pretty Dwarf Jacob's Ladder. (Canada, United States. Height, 6 inches. In bloom second week of May. A very pretty free blooming perennial with violet-blue flowers and small, narrow leaves.

Phlox ovata.—Ovate-leaved Phlox. (United States). Height, 12 to 18 inches. In bloom first week of June. Flowers, rich pink. One of the best coloured phloxes tested. It continues in bloom most of the summer, and is very showy.

Trollius Ledebourii.—Ledebour's Globe Flower, (Siberia). Height, 12 to 18 inches. Flowers, large, orange-yellow. This species has deeper coloured flowers than most of the other sorts, and on this account is highly recommended.

REPORT OF THE CHEMIST.

(Frank T. Shutt, M.A., F.I.C., F.C.S.)

Dr. Wm. Saunders,
Director, Dominion Experimental Farms,
Ottawa.

Ottawa, 1st December, 1898.

Sir,—I have the honour to submit herewith the twelfth annual report of the Chemical Division of the Experimental Farms.

The various branches of work reported on by this Division in previous years have again received attention. As far as was practicable, original investigation and chemical work in connection with experiments on the farms have taken priority, but the large amount of work of an urgent nature that has come in from farmers during the past year has obliged us to relinquish, or at least to leave unfinished for the time, much interesting research work that we had undertaken and hoped now to be in a position to report upon. Every year sees an increase in the number of requests for examination of soils, cattle foods and many other matters pertaining to agriculture. The correspondence yearly makes greater demands upon our time. In consequence of all this there is now a considerable number of samples awaiting examination and analysis. It is our hope to attend to these as opportunity permits. Those who have thus sent samples to the laboratory and have not yet received any report, may rest assured that press of work alone has prevented us from making the desired analysis. All samples are duly recorded in a register as received, and are taken in hand, as time allows, in the same order.

All research and analytical work, whether in connection with our experiments or with samples submitted by farmers, is undertaken with the hope of furnishing results of importance and practical value to Canadian agriculture. This object has been kept well in view during the past year, and we feel assured that the information presented in this report, as well as that given by correspondence, will be found of service by farmers in general and those engaged in one or other of the special branches of Canadian husbandry.

The present report may be briefly summarized as follows :—

The Preservation of Manure.—The results of an extensive investigation on this important subject show (1) the relative value, weight for weight, of fresh and rotted manure, (2) the losses that occur during the rotting of "protected" and "exposed" manure, (3) the effect of rotting on the availability of the plant food contained in manure and (4) the effect of adding ground gypsum to fermenting manure. The data and the conclusions drawn from this investigation will undoubtedly prove interesting and valuable to our readers.

Inoculation with nitragin for the growth of legumes.—This work, commenced in 1897, has during the past season been continued. Though the results are not, perhaps, on the whole, so encouraging as those recorded in last year's report, they nevertheless point to the efficacy of this new agent in promoting the growth of clover and other members of the legume family. Further experiments, tried in various parts of the country, will be needed before we can definitely say whether *nitragin* can be used economically in the field.

Forage Plants, Fodders and Feed Stuffs.—Grouped under this heading are to be found results obtained on the following:—

1. The native prairie hays as grown in Manitoba and the North-west Territories. The composition of hays produced on lowlands (principally sedges) as compared with that of uplands, and their relative feeding value considered.

2. The composition of timothy and brome grass hay as grown at Ottawa. Since brome grass of late years has attracted so much attention, both in Ontario and the North-west, the results of these analyses will undoubtedly be of wide interest.

3. Soja beans as a forage crop for the silo. This is practically a new field crop and has been recommended for ensiling with Indian corn to supply nitrogenous matter and thus make the ensilage nearer a "balanced" ration. Analyses are given depicting the composition of the beans grown under different methods of seeding and culture.

4. Oat feed, oat dust, etc., are by-products in the manufacture of oat meal. They have been largely sold of late to dairymen. Our examination of several samples furnishes information as to their nature and feeding value.

5. Molasses refuse from the sugar refinery. This also, in certain parts of Canada has appeared upon the market as a feeding stuff. The analyses made in the farm laboratories clearly define its character and value as a cattle food.

6. Cocoa shells. This is a waste product from the cocoa and chocolate factory and a highly nitrogenous material that may prove of value, locally, as part of the concentrated or meal portion of the ration.

7. Sugar-beets as grown in British Columbia.

Flours.—This work includes a careful analysis and a critical study of the results of representative samples of Canadian and Hungarian flours.

Soils.—Some of the more important soil examinations made during the past year are here reported on, and suggestions (which will prove of value to others having similar soils) for their treatment and improvement have been added.

Fertilizers.—We present data on several samples of swamp muck recently analysed in the laboratories and also furnish information respecting "Thomas or Basic slag" and "South Carolina Rock," two phosphatic fertilizers now largely advertised in Canada.

Well-waters from farm homesteads.—More than one hundred samples have been received for examination during the twelve months ending 30th November, 1898. Of these seventy-five have been submitted to analysis. In connection with the results of these, certain information has been given on the important subject of the farmer's water supply, which we trust will prove of practical value and lead to greater care being taken in preventing pollution of the farm well.

It should be distinctly understood that samples from *farm homesteads only* can be examined. The printed instructions issued by the Farm should be obtained before sending a water for analysis, since the probability is that otherwise a mistake will be made respecting the quantity required or in the matter of collection and shipment.

In connection with the work of this Division the results of which cannot of necessity appear in the report, we have to speak as follows:—

Correspondence.—From November 30th, 1897, to December 1st, 1898, 1,298 letters were received and 1,904 letters were despatched. Since the greater number of letters received contain requests for information on soils, fertilizers, cattle foods, etc., it is scarcely necessary to add that a considerable portion of my time is taken up with this branch of our work.

Tuberculin.—By direction of the Department of Agriculture we have prepared and forwarded to veterinary surgeons throughout the Dominion 595,320 minims or 9,922 doses of diluted tuberculin during the twelve months ending November 30th, 1898. This is practically three times the quantity sent out in 1897. This work has consumed

much time and has now assumed such large proportions that it becomes necessary in the near future to provide special assistance to carry it on, or the purely chemical work of the division must suffer.

Samples received for analysis.—The appended schedule denotes the number and nature of the samples received at the farm's laboratory since our last report.

SAMPLES received from Farmers for Examination and Report, November 30, 1897, to December 1st, 1898.

—	British Columbia.	North-west Territories.	Manitoba.	Ontario.	Quebec.	New Brunswick.	Nova Scotia.	Prince Edward Island.	Total.	Number still awaiting examination.
Soils	5	......	3	5	9	6	3	.....	31	27
Mucks, mud and marls	1	.....	1	9	3	10	10	16	50	29
Manures and fertilizers	7	1	......	2	2	2	7	2	23	9
Forage plants and fodders	17	10	5	16	......	2	11	2	63	26
Well waters	2	5	8	61	21	2	4	4	107	......
Miscellaneous, including dairy products, fungicides and insecticides	2	6	3	8	6	......	3	5	33	12
	34	22	20	101	41	22	38	29	307	103

As shown above, many of these, for want of opportunity, still await examination. All the waters and samples of a perishable nature have, however, been reported on; the remaining samples, the analysis of which has been necessarily postponed, have been prepared and bottled, so that they can be examined as soon as time permits.

Mineral specimens.—We would again call attention to the fact that it does not come within our province to examine and report upon mineral specimens.

The Assistant Chemist.—In April last, Mr. H. S. Marsh, who had been with us since November, 1894, resigned the post of assistant chemist. The vacancy was filled by the appointment of Mr. A. T. Charron, who entered upon his duties July 1st.

Mr. Charron, who is a graduate of Ottawa University, passed some years ago the Departmental examination qualifying him for the post of Public Analyst in the Dominion, since which time he has had considerable experience in analytial work, both in Ottawa and Montreal. It is with the greatest pleasure that I can bear testimony to Mr Charron's ability and skill as a chemist. He has shown himself a careful and assiduous worker and the lively and intelligent interest he has evinced in the work of the Division has rendered his services of great value. My thanks are due to him for many of the data presented in this report.

I have the honour to be, sir,
Your obedient servant,

FRANK T. SHUTT,
Chemist, Dominion Experimental Farms.

THE PRESERVATION OF BARN-YARD MANURE.

Further investigations into the losses that occur in the rotting of barn-yard manure under different systems of preservation were commenced two years ago.* The analytical work in connection with these experiments was not completed till the early part of the present year, and consequently this is the first opportunity of presenting the results in detail to the farmers of Canada.

THE ROTTING OF MANURE: "PROTECTED" AND "EXPOSED."

Series 1: This experiment consisted in taking two lots of fresh manure, equal in weight and alike in composition, and placing one in a closed shed, the other in an open wooden bin with a practically water-tight floor, both lots being weighed and analysed month by month for the period of a year.

The objects of this investigation, stated briefly, were to ascertain, under the "exposed" and "protected" conditions just described, (1) the losses in plant food (nitrogen, phosphoric acid and potash) that may occur, (2) the changes, as regards availability of the nitrogen, phosphoric acid and potash, that may result, (3) the relative values, weight for weight, of fresh and rotted manures and also of the latter at certain times throughout the fermentation period.

In April, 1896, horse and cow manures, produced at the Experimental Farm, Ottawa, and consisting of the solid and liquid excreta and the litter used in bedding these animals, were taken in equal proportions by weight and thoroughly mixed. Four tons of this resulting manure were placed in a small wooden building which was weather-proof, and a similar amount—four tons—was placed in an open bin constructed with double flooring and sides. The manure, both in the building and in the bin (designated in this report as "protected" and "exposed", respectively) was kept as compact as practicable throughout the experiment, care being taken after each weighing and sampling, to render the manure as close and dense as might be possible by tramping and pounding.

As already stated, samples of each of the manures were taken monthly, the total weights at these periods being also ascertained. The initial and subsequent samplings were done carefully and with thoroughness, and all precautions taken to obtain for analysis representative portions.

Notes on the appearance of the manures were made monthly at the times when the samples were taken. These serve to indicate the degree to which fermentation or decomposition had advanced, at the several periods; in other words, the condition or character of the manures as fermentation proceeded.

The analysis consisted in determining (1) moisture, (2) organic or vegetable matter, (3) ash or mineral constituents, (4) total nitrogen, (5) nitrogen present as ammonia and in nitrates and nitrites, (6) total phosphoric acid, (7) available phosphoric acid, (8) total potash, (9) available potash. The amounts of "total" phosphoric acid and potash obtained were those dissolved out of the manure by hot strong hydrochloric acid (sp. gr. 1·115) at the temperature of boiling water; the amounts of these constituents designated as "available" were obtained by treatment with dilute citric acid (1 per cent) in the cold. We may suppose that the nitrogen present as ammonia, nitrates and nitrites, and the phosphoric acid and potash soluble in dilute citric acid, to be more or less immediately available to plants. The value of these estimations as a means of tracing the conversion of the plant food into assimilable forms will, therefore, be apparent.†

---

* The results of previous experiments in the preservation of barn-yard manure are published in the Report of the Experimental Farms for 1895 and 1896.

†Dr. Bernard Dyer, in 1894, showed that the sap and exudations of rootlets had a solvent action approximately equivalent to that of 1 per cent citric acid solution, and this was therefore the solvent used in the determination of the amounts of "available" fertilizing constituents present.

The composition of the fresh manure experimented with, as revealed by the initial analysis, was as follows:—

	Per cent.
Water	68·61
Organic matter	24·23
Ash or mineral constituents	7·16
	100·00
Total nitrogen	·601
Nitrogen, as ammonia, nitrates and nitrites	·083
Total phosphoric acid	·31
Available phosphoric acid	·19
Potash	·76
Available potash	·68

It will be instructive in passing to compare this manure with that ordinarily produced throughout the country. As regards nitrogen, it is considerably richer than that usually met with, chiefly due no doubt to the fact that greater care is exercised on the Experimental Farm than on the majority of farms in retaining and preserving the liquid portion, and, secondarily, to the liberal diet fed on the Experimental Farm. The manure experimented with is also much above the average in phosphoric acid and potash. These facts are set forth in the following table:—

COMPOSITION OF FRESH MANURE.

Constituents.	Experimental Farm.	Average obtained from other samples.
	Lbs. per Ton.	Lbs. per Ton.
Nitrogen	12·0	7·8
Phosphoric acid	6·2	3·1
Potash	15 2	9·0

THE AVAILABILITY OF THE PLANT FOOD IN FRESH MANURE.

The data on this point are of great interest; a consideration of the foregoing analysis allows us to draw the following important conclusions,

Of the total nitrogen present, 13·8 per cent was as ammonia or in the oxidized form of nitrates or nitrites—compounds of nitrogen that may be utilized more or less directly by the growing plant. In manure that is absolutely fresh, that is, just produced, there is no ammonia and no nitrogen in the form of nitrites and nitrates. The manure which in these experiments we designate as fresh had been accumulating about ten days before the experiment began, and consequently the first stages of fermentation had set in. As a result of this fermentation, these assimilable compounds of nitrogen (representing 13·8 per cent of the total nitrogen) had been formed. Calculated per ton of manure, we have, then, 12 lbs. of total nitrogen, about one and a half pounds of which is immediately assimilable.

Of the total phosphoric acid, 61·3 per cent may be regarded as available. The amount of this element per ton of manure is 6·2 pounds, of which 3·8 pounds is available.

Of the total potash present, no less than 89·5 per cent is soluble. The manure contained 15·2 pounds per ton, of which 13·6 pounds were, we may suppose, immediately assimilable.

NOTE.—The fact that approximately 60 per cent of the phosphoric acid and 90 per cent of the potash in, comparatively speaking, fresh manure are assimilable by crops, is one worthy of remark. In arriving at this we have necessarily assumed Dr. Bernard Dyer's conclusion, already referred to, as correct.

THE CONDITION OF THE PROTECTED AND EXPOSED MANURES AT VARIOUS PERIODS THROUGHOUT THE EXPERIMENT.

The following notes were made when the manures were weighed and samples taken for analysis, monthly, for the period of a year. Both manures rapidly decreased in weight during the first three months, but more especially during the first month of fermentation. From the third month on there was, under the conditions of the experiment, but little decrease in weight of the "Protected" manure, and in the case of the "Exposed" manure the fluctuations in weight after the third month, were principally due to rainfall and evaporation. The total weights of the manures at the periods mentioned are recorded in the first column of table II.

At the end of one month.—Protected manure: quite hot and steaming; considerably "shorter" than at beginning of experiment, but not fully rotted; mould showing in upper six inches of manure.

Exposed manure: not so "short" as protected manure, straw being longer; mould more apparent than in protected manure and showing more or less all through the mass.

At the end of two months.—Protected manure: slightly warm in lower layers; somewhat "shorter", drier and more mouldy than in month previous.

Exposed manure: not quite so dry or so mouldy as protected manure; fairly rotted. (*Vide* foot note.)

At the end of three months: Protected manure; well rotted, short and mouldy; very dry all through. Exposed manure: thoroughly rotted; appears to be in excellent condition; short and quite damp, owing to heavy rains during the previous month.

From this period on, no great differences were to be noticed, though notes taken at the samplings and weighings show that both manures became gradually more homogeneous. For all practical purposes, however, three months, under the conditions of this investigation, were quite sufficient to thoroughly rot the manures, and judging from appearances no benefit was to be derived from fermenting for a longer period. The exposed manure necessarily varied in wetness, according to the rainfall of the preceding month; the protected manure became more and more dry and crumbly. Since the losses of rotted manure by leaching are greater than those of fresh manure, the folly of fermenting manure in exposed piles throughout the greater part of the year, as is the custom with some, becomes apparent.

COMPOSITION OF FRESH AND ROTTED MANURES: PROTECTED AND EXPOSED.

Data representing the percentage composition of the manures taken at twelve stages throughout the experiment are presented in table I. Those of the original manure have already been discussed. We may now consider the composition of the manures and the changes that occur in the condition of the elements of plant food, as rotting proceeds. The losses that necessarily ensue will be spoken of when explaining the results set forth in tables IV and V.

NOTE.—The analytical data for the manure samples of this date are, unfortunately, incomplete, the fire that occurred in the laboratories destroying the samples and many of the results, as the work was in progress.

Building and open bin used in manure preservation experiments. Men engaged in sampling and weighing manure.

TABLE I.

PERCENTAGE COMPOSITION OF FRESH AND ROTTED MANURES, PROTECTED AND EXPOSED.

Manure. (Horse and cow manure in equal parts.)	Water.	Organic Matter.	Mineral Matter or Ash.	Nitrogen. Total.	Nitrogen. As Ammonia Nitrates and Nitrites	Phosphoric Acid. Total. — (Soluble in hydrochloric acid).	Phosphoric Acid. Available. — (Soluble in 1 p.c. citric acid.)	Potash. Total. — (Soluble in hydrochloric acid.)	Potash. Available. — (Soluble in 1 p.c. citric acid.)

NITROGEN.

Protected manure.—At the end of one month the percentage of nitrogen was ·836, as against ·601 in the fresh manure; in other words, weight for weight, the rotted manure contained one-third more nitrogen than the fresh manure. At the end of three months the nitrogen in the rotted manure was, weight for weight of the manures, slightly more than double that in the original. At the close of the experiment, the nitrogen in the rotted manure was, for equal weights of the manures, somewhat more than two and a half times that in the original fresh manure.

The immediately assimilable nitrogen represented by ammonia, nitrates and nitrites, somewhat contrary to expectation, did not increase in the same ratio or in the regular way, as did the total nitrogen, just discussed. Indeed, our results show not only great fluctuations, but frequently that there was a less percentage of nitrogen in these forms as rotting proceeded, than was present in the original manure.

Exposed manure.—As with the protected manure, the percentage of nitrogen increases, so that the fermented manure, weight for weight, is richer in this constituent than the original fresh manure. The ratio of increase is, however, *very much less*, in

part due to the fact that the exposed manure contained more water than that protected, but in part due to a greater loss of nitrogen. At the end of one month the manure contained, weight for weight, one-sixth more nitrogen; at the end of three months, one-third more nitrogen than the original. At the close of the experiment this latter proportion had not materially changed.

In available nitrogen, the amount, though fluctuating, is seldom as large as that in the protected manure. Approximately, the exposed sample contains but one-third to one-fourth that in the protected.

ORGANIC MATTER.

Though not a direct form of plant food, organic matter, as is made clear in Bulletin No. 31 of the Farm series, is a most important and valuable constituent of manure. It is desirable, therefore, that the percentages contained in manures rotted under different conditions should be known.

Protected Manure.—Throughout the experiment the percentage of organic matter steadily increased, and at the expiration of the twelve months, was half as much more as it was at the outset. The original fresh manure contained 24·23 per cent, the manure one year old contained 35·42 per cent.

Exposed Manure.—The percentage of organic matter in the exposed manure steadily decreased, so that at the end of the investigation is was but slightly more than one-half of the percentage contained in the fresh manure. The figures are 24·23 per cent in the fresh and 15·82 per cent in the manure one year old.

PHOSPHORIC ACID.

Protected Manure.—Speaking in round numbers, the phosphoric acid increased in percentage fourfold during the year's rotting; stated otherwise, weight for weight, the rotted manure contains four times as much phosphoric acid as the original.

For every 100 pounds of phosphoric acid present there were 61 pounds available in the fresh manure and 80 pounds so available in the rotted manure at the end of the experiment.

Exposed Manure.—Manure rotted under the exposed condition possessed about double the amount of the phosphoric acid contained in the fresh manure.

Its available phosphoric acid was just half that of the rotted "protected" manure; thus, the "protected" manure contained 1·08 per cent of phosphoric acid at the close of the investigation, the "exposed" contained but ·56 per cent.

POTASH.

Protected Manure,—In the fresh manure, about 90 per cent of this fertilizing constituent may be considered as assimilable. During rotting the total potash increased from ·76 per cent to 2·76 per cent, and the available from ·68 per cent to 2·52 per cent. According to the results obtained in this investigation, fermentation has practically no effect on the availability of the potash compound.

Exposed Manure.—The potash in this manure has increased from ·76 per cent to 1·23 per cent at the end of three months, but at the expiration of twelve months this was found to be reduced to ·96 per cent. This shows an increase only of about one-third, comparing the first and last samples of manure, weight for weight.

Similarly the amount of available potash was approximately only one-third greater at the end than at the beginning of the experiment, the figures being ·68 per cent and ·92 per cent respectively. As in the case of the "total" potash, the percentage of "available" was somewhat greater at the end of three months than at the expiration of twelve months.

The foregoing remarks only outline the composition of these manures and the changes that occurred as rotting proceeded, but they will be sufficient to guide the reader

in the study of the data presented in table I. These results will well repay careful perusal, since they make clear the value, *weight for weight*, of manures rotted under these two conditions of protection and exposure. (*Vide* foot note).

It should be borne constantly in mind, that in the study of the facts revealed by table I., we are not considering the losses in plant food that have followed fermentation. We are simply comparing the percentage composition of manures rotted under different systems; that is, comparing their values, weight for weight. The losses that have ensued under the two systems of rotting will be treated of subsequently.

Since many may be able to more clearly comprehend the facts set forth in table I., if presented in pounds per ton, and a pecuniary value assigned, the following table has been constructed. Nitrogen has been valued at 12c. per pound, phosphoric acid at 5¼c. per pound, and potash at 5½c. per pound, the average price as paid for these elements of fertility in commercial fertilizers. No regard, in these valuations, has been paid to the proportions of the phosphoric acid and potash classed in the table as assimilable, though, of course, we must suppose the available phosphoric acid, for instance, to be of greater agricultural worth than that not so immediately assimilable:—

NOTE.—It is important here to point out that even the "exposed" manure of this investigation, was rotted under conditions much more favourable than those usually and ordinarily existing on the average faam. We therefore feel justified in saying that greater losses of plant food occur in rotting manure generally throughout Canada, than are indicated by the results of this investigation; in other words, the average rotted manures of Canadian farms is much poorer in plant food than the "exposed" manure of our experiment.

In the foregoing tables (I. and II.), the composition of the manures is represented as they were at the end of each month throughout the experiment. In the case of the "exposed" manure, especially, the percentage of water present necessarily varied from month to month. This fact in part accounts for certain apparent discrepancies in the results. Thus, one ton of the exposed manure is said to contain on 29th January, 309 lbs. of organic matter, whereas, for the month previous, and that following, the amounts are stated at 301 and 302 pounds, respectively. These fluctuations, as already remarked, are caused largely by the varying water content, but it is only right to add, not wholly so. The difficulty in obtaining a thoroughly representative sample for analysis from such large masses of wet material, consisting of dung, litter, &c., is very great. There are also the necessary errors of weighing the manures and of analysis. The weighings of the manures, the sampling and the analysis were, however, all done with the greatest care, and, indeed, the general agreement of the data prove that such has been the case. These remarks necessarily apply also to tables III. and IV.

In order to trace more clearly the effect of rotting these manures under the different systems employed, we may eliminate by calculation the water, which we have observed varied from month to month, and compare the amounts of the chief fertilizing elements present as if the manures were in a water-free condition, Table III., series I., contains such data.

Without discussing at any length these data, we may point out that it is apparent that very little, if any, advantage is to be obtained from rotting manure for a longer period than three months, even under the best conditions. The chief fermentation changes, which render more available the manurial constituents and "break-down" the organic matter, have by this time accomplished their work. The manure rotted under exposure continues to get poorer and poorer, especially in organic matter and potash. The protected manure remains practically constant in composition after the third month. The greatest changes due to fermentation (not to leaching) are seen to take place during the first month of rotting.

THE LOSSES THAT OCCUR IN ROTTING "EXPOSED" AND "PROTECTED" MANURE.

By far the more important deductions of this investigation are those relating to the losses that occur under the two systems of preservation used in this experiment, and the effect of rotting upon the availability of the elements of fertility. Table IV., contains in the first column the weights of the manures at the several dates when the samples were taken for analysis. The figures in the columns following have been obtained by multiplying these weights by the percentages of the constituents found by analysis at the dates indicated (see table I.). They consequently represent the amounts of the fertilizing ingredients in the whole mass of the manures at these periods. The last column gives the total value of the nitrogen, phosphoric acid and potash present.*

The importance of these data merits their careful consideration.

*NOTE.—In calculating the pecuniary values we have not taken into consideration the amounts of phosphoric acid and potash that are available, but simply calculated from the "totals" of these constituents present. Were we to assign higher values to the former than to the latter, which we should be quite justified in doing, the differences in value, in favour of the protected manure, would be much greater than those stated in the table.

Organic matter.—In the protected manure the total amount of organic matter was reduced from 1,938 pounds to 774 pounds; in the exposed manure, from 1,938 pounds to 607 pounds.

Nitrogen.—The loss in nitrogen from the protected manure was 10·5 pounds; that from the exposed manure, 17·4 pounds. This means that the former lost practically one-fifth of its nitrogen, while the latter lost something more than one-third.

Phosphoric Acid.—In the protected manure there was virtually no loss of this constituent. Rotting had increased the amount of available phosphoric acid 3½ lbs.

In the exposed manure there was a loss of 3½ lbs. in total phosphoric acid, while of the available phosphoric acid there was only 1 lb. more at the end of the experiment than at the beginning.

Potash.—The total and available potash in the protected manure remained practically constant throughout. There was but little loss, if any.

In the exposed manure. there was a loss of 24½ lbs. of potash (two-fifths of the potash originally present), and the available potash was 21 lbs. less than in the fresh manure.

From the facts represented in table IV., the following percentages of loss have been calculated.

TABLE V.

Loss of Fertilizing Constituents in the Rotting of Manure.

Value of fresh manure $2.61 per ton.

In concluding the discussion on the results obtained in this investigation, we may sum up briefly as follows :—

1. That there is a greater loss of nitrogen and organic matter from the exposed manure than from that protected. The former lost one third of its nitrogen, the latter about one-fifth. Ten per cent more organic matter was destroyed in the exposed than in the protected manure.

2. That there is practically no loss of potash and phosphoric acid from the protected manure.

3. That the exposed rotting manure lost about one-sixth of its phosphoric acid and somewhat more than one-third of its potash.

4. The chief changes, due to fermentation, take place within the first months of rotting, and as far as this experiment goes there is no apparent benefit in rotting for a longer period than three months.

The benefits of rotting manure may be summarized as follows :—

The manure becomes disintegrated and of uniform character throughout, resulting in easier and more uniform distribution in the field and allowing a more intimate mixing with the soil ; the coarse litter is decomposed and its plant food thus made more available ; compounds are formed from the organic matter that more readily produce humus within the soil ; the availability of the nitogen of the solid portion of the manure is increased ; the phosphates are made more assimilable ; there is less weight of manure to haul to the fields ; the larger number of weed seeds that may be present are destroyed.

We may again be permitted to call the attention of the reader to the fact—since it is an important point—that the conditions under which manure is kept ordinarily in barnyards are such as would lead to a much greater loss of fertilizing constituents, both from excessive fermentation and leaching, than resulted even from the "exposed" manure of this investigation.

THE PRESERVATION OF MANURE WITH GYPSUM.

This investigation was undertaken with the view of ascertaining the effect of ground gypsum in retaining the nitrogen of fermenting manure in the pile. Three tons of horse and cow manure, mixed in equal proportions, were allowed to ferment without the addition of any preservative, and an equal weight of the same manure was mixed intimately with ground gypsum or land plaster at the rate of 50 pounds per ton of manure. These lots were fermented at the same time in separate bins inside the small building used in the previous experiment (see illustration). The manures were placed in the building on 15th July, being then fresh, made as compact as possible and not stirred or otherwise disturbed till the close of the experiment, 15th November, when they were again weighed and samples taken for analysis. From time to time both lots of manures were moistened. Both manures, therefore, were, with the exception of the presence of gypsum in the one, rotted under the same conditions.

The results of our analysis of the fresh manure and the same manure rotted alone and with gypsum after four months are preented in Table VI. At the time when the final samples were taken, both manures appeared to be thoroughly rotted.

TABLE VI.

As we noted in the previous investigation the rotted manures are richer in all the essentials of plant food than the fresh manure, weight for weight.

Calculating these data to a water-free basis, we obtain the figures given in Table VII. These permit a closer comparison of the composition of the manures and show the same general result as regards the increase in the percentage of the elements of fertility, as were noticed in the previous experiment.

By multiplying the percentages in Table VI. by the weight of the manures, the data of Table VIII. are obtained. From these we may deduce the losses due to fermentation, and also learn what action the ground gypsum may have had in retaining or fixing the nitrogen which may escape as ammonia, or more strictly speaking, carbonate of ammonia.

In considering the organic matter, it would appear that the presence of gypsum had had a beneficial effect. From this experiment, it seems that gypsum retards to a certain extent the destruction of this constituent.

With respect to nitrogen, however, no useful result is to be observed under the conditions of this experiment from the use of gypsum. The amounts in the manure rotted with and without plaster are practically the same.

Ground gypsum, undoubtedly, may be used to advantage in the stable. The nitrogenous compound in the urine (*urea*), by the aid of certain micro-organisms, always present in the air, is converted very quickly into carbonate of ammonia. This is volatile and will escape if some suitable absorbent or fixer is not present. Gypsum is such a fixer, converting the carbonate into sulphate of ammonia, which is not volatile.

From the results of the investigations under discussion, it might be inferred that the greater part, at all events, of the nitrogen that escapes from fermenting manure is in the free state, that is, as gaseous nitrogen. If the manures had not been kept constantly moist, the results might have been different.

The practical conclusions from this part of this investigation are (1) that the proper place to use gypsum is in the stable, where undoubtedly the greater waste of nitrogen, as ammonia, frequently occurs, and (2) that when the manure heap is kept *compact and moist* there is not any considerable escape of ammonia.

Fermentation, it will be seen (table VIII.) as in the former experiment, has increased the availability of the phosphoric acid.

It is to be noticed that a considerable loss of potash has taken place in both manures. This must be due to a certain amount of drainage from the manures soaking into the board floor upon which they rested. This drainage was no doubt increased by the water used in keeping the manures constantly moist. This result corroborates the conclusions reached from a consideration of the foregoing investigation with exposed manure, namely, that loss of potash cannot be entirely guarded against without a water-tight, concrete floor, if the manure is to be kept moist by rain or artificial means.

SOIL INOCULATION FOR THE GROWTH OF THE LEGUMES.

THE USE OF NITRAGIN IN AGRICULTURE.†

Nitragin is a bacteriological preparation containing the germs that reside in the nodules on the roots of leguminous plants, and which enable the host plant to utilize and appropriate free atmospheric nitrogen. Its use, by inoculation of the soil or seed, has been recommended to induce a more vigorous growth of the legumes, and in order to test its practital value for this purpose, experiments at the Central Farm were begun during the season of 1897. The results of these investigations and the deductions therefrom were set forth in the report for last year. A distinct increase in the amount of nitrogen, presumably from the application of nitragin, was observed in the crop in several of the inoculated series of plants.

To obtain further evidence on this subject, experiments of a similar character have been conducted during the past season, the treatment and method of culture being practically the same as in 1897.

PEASE.

The seed was sown on 2nd June; plants thinned to 11 in each pot; experiment closed and samples taken on 4th August, when most of the pods were fully formed. The vines were, however, still quite green and possessed some flowers. Culture used, *Pisum sativum.*

			Grams.

" 15 and 16, soil inoculated,	"	" ..	107·9
" 17 and 18, seed inoculated,	"	" ..	132·0

†A detailed account of Nitragin, its nature and uses, and of the principles of inoculation for free nitrogen appropriation in the growing of clover, pease, beans, etc., is to be found in the report of this Division for 1897, p. 141, et seq.

All the roots of the untreated pots possessed some nodules, showing that the soil used contained naturally the germs. It would appear that the micro-organisms, which thus assist the growth of the legumes, are widely prevalent in the soil of this district, since but little difficulty is experienced in obtaining a good crop of clover, pease, etc.

The nodules on the roots of the "soil inoculated" plants were apparently in about the same number as on the untreated plants. The effect of the nitragin, therefore, as judged by abundance of nodules, was not noticeable.

On the roots of the "seed inoculated" plants the nodules were more numerous and larger than on either of the preceeding.

The analytical data are presented in the following table :—

TABLE I.

PEAS : WEIGHTS OF CROPS, AMOUNTS OF NITROGEN, ASH CONSTITUENTS AND ORGANIC MATTER.

Sown, June 2nd, 1898. — Cut, Aug. 4th, 1898.	Pots 13 & 14. — Not inoculated.			Pots 15 & 16. — Soil inoculated.			Pots 17 & 18. — Seed inoculated.

" nitrogen	·450	·148	·598	·535	·172	·707	·546	·193	·739
" ash or mineral constituents..	2·58	3·96	6·54	2·87	2·42	5·29	2·52	6·42	8·94
" organic matter.	14·29	3·55	17·84	16·11	3·56	19·67	17·86	5·22	23·08
" "dry matter"..	16·87	7·51	24·38	18·98	5·98	24·96	20·38	11·64	32·02

Taking an increase in weight of crop as evidence of the activity of nitragin, we may conclude that both in the soil and seed inoculated series this fertilizing agent has been effective. In the first place, it is to be noticed that the weights of the roots, as well as of the stems and leaves, are greater from the treated than from the untreated plants. Secondly, that the amounts of nitrogen, both in foliage and roots, of the inoculated plants exceed those in the plants from the untreated pots. Thirdly, that the amounts of "dry matter", that is, the organic and mineral substances of the plant, are also greater in the crops of the treated than in the untreated pots, showing greater assimilation on the part of the treated plants.

The nitrogen in the roots in all the trials was approximately one-third that in the stems and leaves, or one-fourth of the whole nitrogen present.

Comparing the value of soil inoculation with that of seed inoculation, this experiment shows that the latter was more effective.

In tables II. and III. we record the percentage composition of the fresh material and of the "dry matter." They allow a closer comparison of the composition of the pea plants, treated and untreated, and furnish corroborative evidence in favour of one or two conclusions drawn from last year's experiments.

The data of Table II. show that as regards the percentage composition of the foilage (stems and leaves) there is practically no difference between the treated and untreated plants. The larger amounts of nitrogen contained in the former are therefore due to the larger weight of foliage, produced presumably through the agency of the *nitragin*.

TABLE II.

PEAS: PERCENTAGE COMPOSITION OF FRESH MATERIAL.

Constituents.	Pots 13 & 14. — Not inoculated.		Pots 15 & 16. — Soil inoculated.		Pots 17 & 18. — Seed inoculated.	
	Stems and Leaves.	Roots.	Stems and Leaves.	Roots.	Stems and Leaves.	Roots.
Nitrogen	·69	·58	·709	·53	·639	·416
Ash or mineral matter	3·95	15·53	3·81	7·47	2·95	13·81
Organic matter	21·92	13·93	21·32	10·98	20·88	11·22
Dry matter	25·87	29·46	25·13	18·45	23·83	25·03

TABLE III.

PEAS: PERCENTAGE COMPOSITION OF DRY MATTER.

Constituents.	Pots 13 & 14. — Not inoculated.		Pots 15 & 16. — Soil inoculated.		Pots 17 & 18. — Seed inoculated.	
	Stems and Leaves.	Roots.	Stems and Leaves.	Roots.	Stems and Leaves.	Roots.
Nitrogen	2·70	1.97	2·82	2·87	2·68	1·66
Ash or mineral matter	15·28	52·71	15·15	40·46	12·38	55·19
Organic matter	84·72	47·29	84·85	59·54	87·62	44·81

Though there are some differences in the composition of the dry matter of the treated and untreated plants, these are slight and may be partly accounted for by the unavoidable errors of analysis. It is to be noticed that the composition of the pea plant throughout the series is quite similar. It is not apparent, therefore, from this investigation as some suppose, that the plants inoculated with nitragin are relatively richer in nitrogen than those not so treated In this connection, however, we should state that the check or untreated plants were not grown in sterilized soil, so that the present results do not altogether refute that conjecture. In last year's report we said that "the larger amount of nitrogen in the treated crop is rather due to a greater development of root or foliage or both, under the stimulating effect of the micro-organisms furnished by the preparation." This deduction receives confirmation from this year's work.

HORSE BEANS.

The seed was sown on 3rd June, plants thinned to 11 in each pot ; experiment closed and samples taken August 30th. Culture used ; *Vicia faba.*

Grams.

Pots 7 and 8, untreated, 11 plants, stems, leaves and roots......302·5
Nodules large, but not numerous.

Pots 9 and 10, soil inoculated, 11 plants, stems, leaves and roots...324·0
Nodules large and very numerous.

Pots 11 and 12, seed inoculated, 11 plants, stems, leaves and roots..261·5
Nodules, about the same as in 7 and 8.

The data obtained from this series are as follows :—

TABLE IV.

HORSE BEANS: WEIGHTS OF CROP, AMOUNTS OF NITROGEN, ASH CONSTITUENTS AND ORGANIC MATTER.

Sown, June 3rd 1898. — Cut, August 30th 1898.	Pots 7 & 8. — Not inoculated.			Pots 9 & 10. — Soil inoculated.			Pots 11 & 12. — Seed inoculated.		
	Stems and Leaves.	Roots.	Total.	Stems and Leaves.	Roots.	Total.	Stems and Leaves.	Roots.	Total.

" of nitrogen	1·10	·51	1·61	1·10	·5	1·60	·94	·30	1·24
" ash and mineral constitutents.	4·89	15·1	19·99	4·73	12·2	16·93	4·89	6·33	11·32
" organic matter .	31·71	13·48	45·19	32·91	11·7	44·61	28·70	7·87	36·57
" "dry matter" .	36·60	28·58	65·18	37·64	23·9	61·54	33·59	14·20	47·79

The largest yield of crop was obtained from the "soil inoculated" plants; the smallest, from the "seed inoculated."

With regard to nitrogen, the amounts in the untreated and "soil inoculated" plants are practically identical; that in the "seed inoculated" plants is somewhat less.

The results in this series with horse-beans are certainly not such that definite conclusions may be safely drawn therefrom. With the "soil inoculated" plants there was, apparently, a benefit from the nitragin, but on the other hand, better returns were obtained from the untreated than from "seed inoculated" plants. The cause for this unsatisfactoriness is difficult to find, more particularly as the experiment was carried out in a similar way to that of 1897, when nitragin gave marked results with horse-beans. It is quite possible that the "culture" used had become impaired through the action of time, light or warmth. The manufacturers of nitragin, Messrs. Meister, Lucius & Bruning, Höchst am Main, Germany, now add a special caution on these points and say that it should be used within four weeks of the date of purchase at the latest.

In tables V. and VI. the percentage composition of the fresh material and dry matter is given.

TABLE V.

HORSE BEANS: PERCENTAGE COMPOSITION OF FRESH MATERIAL.

Constituents.	Pots 7 and 8. — Not inoculated.		Pots 9 and 10. — Soil inoculated.		Pots 11 and 12. — Seed inoculated.	
	Stems and Leaves.	Roots.	Stems and Leaves.	Roots.	Stems and Leaves.	Roots.
Nitrogen	·425	1·17	·402	1·10	·425	·764
Ash or mineral matter....	1·89	34·70	1·72	24·4	2·20	16·03
Organic matter........................	12·23	31·00	12·03	23·4	12·93	19·92
Dry matter	14·12	65·70	13·75	47·8	15·13	35·95

TABLE VI.

HORSE-BEANS: PERCENTAGE COMPOSITION OF "DRY MATTER."

Constituents.	From Pots 7 and 8. — Not inoculated.		From Pots 9 and 10. — Soil inoculated.		From Pots 11 and 12. — Seed inoculated.	
	Stems and Leaves.	Roots.	Stems and Leaves.	Roots.	Stems and Leaves.	Roots.
Nitrogen	3·0	1·80	2·92	2·09	2·81	2·12
Ash or mineral matter	13·35	52·83	12·58	51·14	14·55	44·60
Organic	86·65	47·17	87·42	48·86	85·45	55·40

The results in table V. show that differences of note exist in the composition of the roots, mainly due to varying percentages of water. While it might be interesting from a scientific standpoint to discuss the cause for this, we are at present unable to draw any conclusions of practical value, and can only hope that future investigations may give clearer evidence as to the value of this preparation.

PLOT EXPERIMENTS WITH NITRAGIN: CLOVER, PEAS, BEANS.

The experiments, the results of which have already been recorded were made in pots of special construction, as explained in our report for 1897. In order to test the effect of nitragin in the field, an area of 10 square yards was staked off and fertilized by the following mixture :—Superphosphate, 12 ozs. Muriate of potash, 4 ozs. These chemicals were well mixed with sand previous to application in order to facilitate uniform distribution. The soil selected was almost pure sand, humus and nitrogen being present only in exceedingly small quantities. The area was sown 13th June, as follows :—

Clover .... 2 rows, seed untreated, 2 rows, seed inoculated.
Horse-beans ...... 2 rows, seed untreated, 2 rows, seed inoculated.
Pease............ 2 rows, seed untreated, 2 rows, seed inoculated.

Clover.—On 28th October, the experiment was closed. The plants from four feet in each row were carefully dug and weighed. Culture used, *Trifolium pratense.*

Clover.	From untreated rows.	From inoculated rows.
Weight of foliage, green	8 oz.	9½ oz.
" roots, green	8 "	9 "
Total	16 oz.	18½ oz.
Weight of foliage, air-dried	3 oz.	3¾ oz.
" roots, air-dried	2½ "	3¼ "
Total	5½ oz.	7 oz.

The crop from the inoculated seed was much more luxuriant than that from the untreated seed, and the above results show that the yield was considerably heavier. In this case it would appear that the nitragin had exerted a beneficial influence of a most marked character.

Horse-beans.—The beans were allowed to grow until 10th October, when the crop was dug. The best twenty-four plants from the untreated rows were selected and a similar number of the best plants from the inoculatad seed were taken. The data as to weights were obtained from these selected plants. The roots were weighed with the stems and leaves.

Horse Beans.	From untreated seed.		From inoculated seed.	
	Lbs.	oz.	Lbs.	oz.
Weight of 24 best plants, green	1	11	1	10½
" " air-dried	.	7		7

It is not apparent from these results that the nitragin was of of any value in encouraging the growth of the horse-beans. In the pot experiments with horse-beans, already recorded, it will be remembered that this year no result from the nitragin was observed, which lends further weight to the doubt regarding the vitality of the preparation used.

Pease.—The plants, roots and foliage, were gathered on 9th August, six feet from the untreated and inoculated seed rows being taken for the yield.

Pease.	From untreated rows.		From inoculated rows.	
	Lbs.	oz.	Lbs.	oz.
Weight of plants, green	1	15	2	½
" air-dried		8½		9¼

Here again, though the difference is not a large one, the crop from the inoculated seed is the larger.

Our pot and plot experiments with nitragin for 1898 may, therefore, be said on the whole to confirm the results recorded in last year's report, and furnish further evidence towards establishing the usefulness of this agent in fostering the growth of the legumes.

FORAGE PLANTS, FODDERS AND FEEDING STUFFS.

THE GRASSES OF THE UPLANDS AND LOWLANDS OF MANITOBA AND THE NORTH-WEST TERRITORIES.

Information on the relative feeding value of grasses is useful to all engaged in stock raising and stock feeding, but especially so, we may say, to farmers and ranchmen of Manitoba and the North-west Territories, where frequently the native grasses must be relied on to supply the chief cattle fodder.

In order to gain further knowledge on this subject, as well as to be in a position to answer the many questions sent us repecting the relative merits of the *native grasses* and hays as grown on the *uplands* and *sloughs*, respectively, in the Canadian North-west, we have during the past season submitted a number of such grasses to analysis. Nos. 1 to 5, inclusive, were collected and forwarded by Mr. S. A. Bedford, Superintendent of the Experimental Farm, Brandon, Manitoba; Nos. 6 to 11, inclusive, by Mr. Angus Mackay, Superintendent of the Experimental Farm, Indian Head N.W.T.; No. 12 was received

from Col. Herchmer, Comptroller N.W.M.P., Regina, N.W.T.; No. 13 was sent by Mr. J. A. Smith, Saskatoon, N.W.T. The following notes regarding the botanical character of the samples were kindly furnished by Dr. Fletcher, Botanist of the Farms, who carefully examined these grasses on their arrival. For the other particulars I am indebted to Mr. Bedford and Mr. Mackay.

No. 1.—Grown at St. Norbert, 12 miles S.E. of Winnipeg, Man., on a stony, clay loam. *Lowland* (open prairie) partly flooded in June. Probable yield 2 to 2½ tons per acre. 1898 crop. The sample consisted almost entirely of the barren stems of the following sedges, Carex aristata and Carex stricta, the fine stems of the latter preponderating*.

No. 2. Grown at St. Vidal, 5 miles S. of Winnipeg, Man., on clay loam. *Lowland* (open prairie); wet in June. Probable yield, 2 tons per acre. 1897 crop. The sample consisted chiefly of barren stems of carices and grasses in equal proportion. Probably Carex stricta and Deyeuxia neglecta (Neglected Blue-joint), with a few fragments of Potentilla.

No. 3. From Red River Valley, 10 miles N. of Winnipeg on clay loam. *Lowland*, rather wet in June. Cut, 1st July. Probable yield about 2½ tons per acre. It consisted of fine, barren stems of Carex, probably straminea.

No. 4. Grown in Manitoba, on *Lowland*. The sample consisted entirely of a a sedge probably Carex aristata.

No. 5. From West Selkirk, 23 miles N. of Winnipeg; grown on black, medium loam, *Upland*, and well drained; yield, 1 to 1½ tons per acre; 1898 crop. This sample consisted chiefly of the following grasses in approximately equal proportions: Poa serotina (Fowl Meadow grass), Poa pratensis (June grass), and Phleum pratense (Timothy). Probably one-fourth of sample was made up of weeds, including Stinkweed, Canada Thistle, Heliopsis, Dandelion and leaves of Milfoil.

No. 6. North-west Territories. *Lowland* grass. It consisted chiefly of Deyeuxia confinis (Rough Pony grass), but contained some Hordeum jubatum (Squirrel-tail or wild barley grass), and Glyceria aquatica (Reed Meadow grass).

No. 7. North-west Territories. *Lowland* grass. Consisted entirely of Fluminia arundinaceae (white top) and had been cut when the seeds were about half ripe.

No. 8. North-west Territories. *Lowland* grass. Chiefly Deyeuxia confinis, with a few stems of Hordeum jubatum and Beckmannia.

No. 9. North-west Territories. *Upland* grass. Chiefly Festuca scabrella (Harsh fescue), Agropyrum glaucum (Colorado Blue stem) and Agropyrum caninum (Bearded Wheat grass; also a few stems of Stipa spartea (Spear grass), and Koeleria cristata (Western June grass).

No. 10. North-west Territories. *Upland* grass. Chiefly barren stems of the following grasses: Agropyrum glaucum, A. caninum, Festuca scabrella. There were also in the sample Stipa spartea, Avena pratensis and leaves of wild rose and Artemisia.

No. 11. North-west Territories. *Upland* grass. Very similar to Nos. 9 and 10, consisting of Agropyrum glaucum and A. caninum, mixed with a little wild rose and Western snowberry.

No. 12. From Regina, N.W.T.; sample of hay as fed to horses of North-west Mounted Police. It consisted entirely of the sedge, Carex aristata.

No. 13. From Saskatoon, N.W.T., consisted entirely of Sporobolus cuspidatus, generally considered a grass of but little agricultural value.

The foregoing data may be summarized as follows:—

Lowland hay from Manitoba, Nos. 1, 2, 3, and 4.
" " North-west Territories, Nos. 6, 7, 8 and 12.
Upland hay from Manitoba, No. 5.
" " North-west Territories, Nos. 9, 10 and 11.

---

* The carices are perennial grass-like plants of the sedge family and are characterized by solid, generally triangular, stems and rough-margined leaves.

In order to understand the significance of the data contained in the foregoing table, it is necessary to know somewhat of the nature and functions of the nutritive constituents of fodders. We accordingly furnish this information briefly in the following paragraphs, referring our readers to previous reports for a more detailed account of the facts in this connection :

Albuminoids.—A collective name applied to the nitrogenous organic substances. They are the most valuable of all fodder constituents, and are essential to the formation of muscle, cartilage and the tissues generally, and of the animal fluids, blood and milk. Hence, they are known as "flesh formers." Though their principal office is repairing waste and making new tissue, they also serve to develop heat and energy when fat and the carbo-hydrates are lacking or in insufficient quantities. They may also serve for fat production. Whether animals are laying on flesh, producing wool or milk, or working, a supply of albuminoids is necessary, and experience has shown that economic feeding consists largely in obtaining these constituents at a minimum cost and feeding them in correct quantities.

Fat.—This ingredient has a high nutritive value, and in this respect ranks next to the albuminoids. By its combustion it generates the greater part of the heat of the body. Further, it is readily transformed into fatty tissue in the animal. It aids the digestion and assimilation of the albuminoids and preserves them in the animal economy from undue waste. It is the chief energy-producing constituent.

Carbo-hydrates. Consist of sugars, starch, gums and allied substances, and form a large percentage of the organic matter of plants. They are readily assimilated and oxidized in the animal system, producing much heat and energy. Under certain circumstances they may serve for fat production. They are not stored up by the animal. Carbo-hydrates are frequently classed as "Nitrogen-free extract."

Fibre.—Compared with the constituents already discussed, fibre has a low nutritive value. It forms the woody parts of the stems and leaves of plants and a large part of the hull or husk of seeds. As a rule, the fibre becomes harder and less digestible as the plant approaches maturity. In chemical composition and function as a food, fibre is similar to the so-called carbo-hydrates.

Ash or Mineral Matter.—This contributes to the formation of bone and supplies the tissues throughout the body with the minute quantity of mineral matter they require. It also replaces those saline substances daily excreted.

It will be observed that the Lowland hay is chiefly, sometimes wholly, composed of sedges, which are usually considered as decidedly inferior to the true grasses in feeding value. It is quite doubtful if the sedges are as palatable or digestible as the grasses, being, as a rule, somewhat harsh and tough ; yet we have the testimony of many ranchers and stockmen that both horses and cattle thrive well and fatten upon hay entirely made up of sedges. Colonel Herchmer, who sent sample No. 12, informs us that the horses of the North-west Mounted Police eat the sedge hay with avidity and keep in good condition.

The principal sedge in these lowland hays is *Carex aristata*. In albuminoids it compares most favourably with many grasses, and indeed all the data show it to have nutritive qualities of a high order. The various analyses of this sedge here tabulated lead us to infer the samples were not all obtained at the same stage of growth. We may presume that the richer samples are from the earlier cut hay, since in all probability, as with the grasses, the sedges deteriorate as they ripen.

This series contains too few samples of Upland native hay to allow any decisive conclusions being drawn as to their relative merits compared with hay from lowlands. Indeed, the differences, as revealed by the analytical data, are by no means marked. The following averages, prepared from the foregoing table, are, however, interesting :—

Hay.	Number of Samples.	Water.	Albuminoids.	Fat. (Ether extract.)	Carbo-hydrates.	Fibre.	Ash.
Lowland hay, principally sedges	8	6·96	8·03	2·91	44·09	31·37	6·64
Upland hay, grasses with weeds	4	6·56	8·39	3·44	43·10	30·71	7·80

The analysis of the hay of Sporobolus cuspidatus (No. 13) from Saskatoon, shows this to be rather a poor grass and decidedly inferior as regards albuminoids to the other hays of this series.

As pointed out in Bulletin No. 19, grasses, like all cereals, are particularly susceptible to environment, improving greatly under cultivation. The rich fertile soils of Manitoba and the North-west Territories should be conducive to the growth of grasses containing high percentages of albuminoids, and we may, therefore, expect that the native grasses of the prairies will under cultivation become still more nutritious than the present results indicate. This deduction must not be understood as in any sense contradictory to the statement made from previous work (Bulletin 19) that these North-west hays are highly nutritious and furnish a coarse fodder of valuable feeding qualities. Regarding the sedges, we must admit to some surprise in finding them compare so well with the grasses; nevertheless it is only to be expected that as the growing of grasses receives more attention in the North-west their use will become confined to certain more or less restricted areas.

TIMOTHY AND BROME GRASS HAYS.

Attention was directed to the composition and feeding value of Brome grass in the report of the Division of Chemistry for 1897. The analyses of Brome hay, the results of which are there stated, were made on samples grown on the Experimental Farm, Indian Head, N.W.T. The data showed that this hay possessed nutritious qualities of a high degree.

During the past year we have made a comparative study of the hays of Timothy and Brome grass as grown on the Central Farm, Ottawa, during the season of 1897. Both grasses were cut when considered in the best condition, the samples were taken in February from the barn. The analytical data are presented in the following table:—

COMPOSITION OF THE HAYS OF TIMOTHY AND BROME GRASS, GROWN ON CENTRAL EXPERIMENTAL FARM, OTTAWA, 1897.

Hay.	Moisture.	Albuminoids.	Fat (Ether extract).	Carbohydrates.	Fibre.	Ash.
Timothy hay	9·72	5·94	5·38	43·25	31·30	4·41
Brome grass hay	10·76	6·61	4·51	41·01	31·86	5·25

The nitrogenous compounds, grouped under the term albuminoids, are the most important from a feeding standpoint, and in this regard the Brome grass is seen to be somewhat the better of the two. Stated in pounds per ton, we have the following figures:—

	Albuminoids pounds per ton.
Timothy	118·8
Brome grass hay	132·2

By calculating our data to a water-free basis, we may make a closer comparison of the composition of the real cattle food in the two hays.

COMPOSITION OF THE "DRY MATTER": TIMOTHY AND BROME GRASS HAYS.

Hay.	Albuminoids.	Fat (Ether extract.)	Carbohydrates.	Fibre.	Ash.
Timothy hay...	6·58	5·96	47·90	34·67	4·89
Brome grass hay..............................	7·40	5·05	45·95	35·69	5·91

SOJA BEANS *(Soja hispida.)*

During the season of 1897, this annual legume was first tried as a field crop on the Central Farm. The results obtained gave promise of it becoming a valuable fodder for siloing in conjunction with corn. The indications were that it could be grown with greater certainty of success than horse beans—being better able to withstand drought and hot weather. Soja beans share with other legumes the property of being rich in nitrogenous matter.

Further experiments in growing this crop have been made during the past summer, the details and results of which will be found in the report of the Director and Acting Agriculturist for the current year. In connection with those results, we here present analytical data obtained from plants which had been grown with varying distances between the rows and from crops sown at different dates; the object of the investigation being to ascertain what effect, if any, these conditions and factors had upon the nutritive value of the crop.

In the first series, six average-sized plants, from the crop sown 26th April, were taken, severally, from rows (a) 3 feet apart, (b) 2 feet 6 inches apart, and (c) 2 feet apart.

In the second series, a similar selection was made from the crop sown 17th May, the drills or rows being (a) 21 inches apart, (b) 14 inches apart, and (c) 7 inches apart.

All the samples were taken on 12th September, the plants being quite green, well podded and in good condition generally.

The analytical data showing the composition of these plants have been arranged in the following tabular form:—

SOJA BEANS—PERCENTAGE COMPOSITION OF FRESH MATERIAL.

Soja Beans.	Water.	Albuminoids. (Crude Protein.)	Fat. (Ether Extract.)	Carbo-hydrates. (Nitrogen,—free Extract.)	Fibre.	Ash.
Soja Beans, sown 26th April, cut 13th Sept.,						
" " " drills 3 ft. apart.	71·25	2·58	1·53	13·68	8·85	2·11
" " " 2 ft. 6 in. apart	71·89	2·80	1·71	12·52	8·99	2·09
" " " 2 ft. apart.....	73·16	2·65	1·15	12·00	9·08	1·96
Average........................	72·10	2·68	1·46	12·73	8·97	2·05
Soja Beans, sown 17th May, cut 13th Sept.,						
" " " drills 21 in. apart....	74·03	2·62	·89	11·57	8·85	2·04
" " " 14 in. apart....	71·48	2·22	1·01	14·42	8·79	2·08
" " " 7 in. apart	72·64	2·19	1·21	13·39	8·53	2·04
Average	72·72	2·34	1·04	13·13	8·72	2·05

It is not observable in the first series that the varying distances between the drills has had any *marked* effect upon the composition of the plants; the differences, as revealed by the foregoing results, being small and irregular, might legitimately be attributed to other causes In the second series, the later sown plants, those planted with the greatest distance between the rows, are somewhat the richer, since they contain a slightly higher percentage of nitrogenous compounds (albuminoids).

Comparing the composition of the plants from the early and late sowing, we again notice but very little difference. Such as there is, however, is in favour of the earlier sown beans.

To enable the reader to form some estimate of the food value of this new crop, as compared with other legumes, we append the following table, containing results obtained in the Farm laboratories during recent years together with other data gleaned from the publications of the United States Experiment Stations:

PERCENTAGE COMPOSITION OF LEGUMES.

Name.	Water.	Albuminoids.	Fat.	Carbohydrates.	Fibre.	Ash.
Red Clover, in bloom	72·70	4·30	·90	13·40	6·50	2·20
Alfalfa	71·75	4·84	·97	12·39	7·39	2·66
Serradella, in bloom	79·85	2·87	·74	9·95	3·45	3·12
Bokhara Clover, in bloom	76·52	2·77	·44	12·06	6·59	1·62
Vetch, in bloom	83·90	4·04	·63	6·19	3·24	2·00
Cowpea	86·03	3·25	·62	5·34	2·87	1·89
Beans, Broad Windsor, in bloom	84·59	3·33	·63	5·67	4·14	1·64
" English Horse "	89·24	2·75	·73	2·26	3·71	1·09
" Telephone "	83·81	2·99	1·00	6·79	3·70	1·71
" Soja "	72·10	2·68	1·46	12·73	8·97	2·05

BY-PRODUCTS OF THE OAT: OAT DUST: OAT FEED.

In the manufacture of oatmeal, now so largely and almost universally used at breakfast, several by-products are formed, which find a more or less ready sale as feed—more especially for cows—under the name of oat feed, oat shorts, oat dust, oat dust feed, etc. These may vary greatly in character and feeding value, according to the part of the oat grain predominating and the presence or absence of mill sweepings. The hulls and the hair of the kernel probably form the basis of most of the feeds known as oat dust, and must be considered of low, or, at best, but medium feeding value. There are feeds, however, sold sometimes under the name of oat shorts and oat feed that contain large quantities of broken grain, a very small proportion of hulls, and no sweepings. These have a clean, bright appearance, are heavy, close and fine and must be considered as valuable feed, especially at the price they can frequently be obtained from the oatmeal mills.

Many correspondents during the past year have made inquiries respecting the value of these by-products, and several samples of these new feeding stuffs have been received for analysis. The results obtained from their examination are tabulated as follows:—

COMPOSITION OF "OAT FEED", "OAT DUST", "OAT SHORTS", &c.

No.	Sent by.	Moisture.	Albuminoids.	Fat.	Carbohydrates.	Fibre.	Ash.
1	T. S. Eager, Heckston, Ont	5·20	17·93	6·54	56·00	9·92	4·41
2	Robt. Holmes, Langton, Ont	5·06	11·25	5·08	51·68	20·24	6·69
3	McKay Milling Co., Ottawa, Ont	5·25	11·02	5·09	51·16	21·43	6·05
4	Thos. Fuller, Trenton, Ont	5·71	12·81	5·83	57·82	13·40	4·43
5	C. E. F., Ottawa, Ont	6·69	12·81	3·97	45·78	18·98	11·77

No. 1. Was sent by T. S. Eager, Heckstone, Ont., and purported to be a sample of "oat shorts" from the Kemptville Milling Co., and was selling at about $10.00 per ton. It was the best of all the samples examined. In its percentages of albuminoids and fat, the two most important constituents, it stands highest, and in fibre, the least valuable element, it is the lowest. It must certainly be considered a feeding stuff of high value.

No. 2. Forwarded by Robert Holmes, Langton, Ont., was labelled "Oat Dust from the Tilson Mills, Tilsonburg, Ont." This and the following samples are inferior in feeding value to No. 1. They are somewhat similar as regards composition, though No. 4 should rank next in value to No. 1, owing to its low percentage of fibre.

No. 3. Obtained from the McKay Milling Co., Ottawa, Ont. A good average sample.

No. 4. Sent by Thomas Fuller, Trenton, Ont., and labelled "Oat Meal Dust" from Messrs. Sadler, Dundas & Flavelle Milling Co., Lindsay, Ont.

No. 5. Is a sample from the "cleaning up" of oats on the Central Experimental Farm, and is consequently somewhat inferior to the feeds just discussed.

A mechanical separation of these feeding stuffs was made with the results found in the following table:—

OAT FEED, OAT DUST—MECHANICAL SEPARATION.

Material.	FINE. — (Passed mesh $\frac{1}{38}$ inch.)	MEDIUM. — (Passed mesh $\frac{1}{18}$ inch.)	Hulls.
No. 1—Oat shorts	65·5	30·0	4·5
2—Oat dust	52·0	30·0	18·0
3— "	44·0	40·0	16·0
4—Oatmeal dust	43·0	28·0	29·0
5—Oat screenings	38·0	40·0	22·0

As before remarked, the larger the proportion of "fine" and "medium", the better quality, in all probability, will be the feed. A careful scrutiny will often enable the farmer to arrive at a fair estimate as to the worth of these materials.

Professor Henry, in his work entitled "Feeds and Feeding," gives the following data as representing the digestible nutrients in oats and their by-products:—

DIGESTIBLE NUTRIENTS OF OATS, OATMEAL, OAT DUST, ETC.

Name of Feed.	Dry Matter in 100 Pounds.	Digestible Nutrient in 100 Lbs.		
		Albuminoids.	Fat.	Carbohydrates.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Oats	89·0	9·2	4·2	47·3
Oat Meal	92·1	11·5	5·9	52·1
Oat Feed or Shorts	92·3	12·5	2·8	46·9
Oat dust	93·5	8·9	5·1	38·4
Oat hulls	90·6	1·3	·6	40·1

Until quite recently, oats, it may be said, were grown almost exclusively as feed for animals, and more especially for horses. Since preparations of oats are now so

popular for human consumption, the probabilities are that the supply of these by-products will increase. Dairymen and stockmen, therefore, will do well to know that these materials are exceedingly variable and that good judgment must be exercised in their purchase.

FEEDING VALUE OF MOLASSES REFUSE OR SYRUP.

In the refining of sugar, especially that made from the beetroot, a by-product of the nature of molasses is obtained from which it is impossible with profit to crystallize the remaining sugar, owing to the presence of albuminous materials and saline matter, which latter consists more especially of salts of potash. This molasses refuse has been manufactured on the European continent into a cattle food by being mixed with meals of various kinds, and sometimes with turf or moss litter, and subsequently dried and pressed. The product is a "cake", which has been used with great success for milch cows, fattening stock and horses. When the molasses is fed by itself, that is, unprepared, in large quantities it loosens the bowels; but fed judiciously say, in quantities of 2 or 3 pounds daily as a part of a well balanced ration—it has given excellent results and has proved itself a valuable and economical feeding stuff.

In the early part of the present year, inquiries were received from correspondents in Nova Scotia and Quebec as to the composition and value of this crude syrup, and samples were forwarded from General J. W. Laurie, Oakfield, N.S., and Mr. James W. Stairs, Halifax, N.S., for examination. These samples were duly analysed, with the following results:—

COMPOSITION OF MOLASSES REFUSE.

	No. 1.	No. 2.
Water	24·89	26·42
Cane sugar	50·27	50·05
Glucose	1·95	5·00
Nitrogenous organic matter	7·81	6·85
Nitrogen-free organic matter (undetermined)	5·98	3·10
Ash or mineral matter	9·10	8·58
	100·00	100 00

As regards the important feeding constituents, these samples are practically identical, so that individual consideration will not be necessary.

The large proportion of sugar—which we must regard as immediately digestible food—makes this material undoubtedly a very valuable feed stuff.

Though not wanting in nitrogenous matter, its use for due economy should be supplemented with a certain proportion of some concentrated meal or meals rich in flesh-forming constituents.

The large percentage of "ash" is to be noted, one-half of which is potash. It is the presence of this, no doubt, that is the cause of the looseness of the bowels in cattle fed above a certain quantity per diem. When symptoms of this condition are observed, the quantity of molasses fed should be reduced. Since the potash is not retained by the animal, but is eliminated by the kidneys, the urine will be especially rich in this element and, therefore, should be carefully preserved by the use of absorbent bedding.

General Laurie, who has fed the molasses to fattening steers (at the rate of from 3 to 5 pounds per diem), diluted somewhat and poured upon the cut roughage or coarse fodder, reports that the animals develop a great liking for it, and that to all appearances it is giving good results.

The most important points in favour of this new feeding stuff may be stated as follows:—(1) that it contains a large percentage of sugar, the most assimilable form of carbo-hydrates found in cattle feeds. This class of nutrients is used by the animal to

the production of energy the maintenance of the vital heat and the production of fat; (2) that it stimulates the appetite, and (3) probably increases the digestibility of the other constituents of the ration.

The cost of the crude syrup we understand, is three-quarters of a cent per pound at the refinery, and at this price it should prove a profitable feeding stuff. The amount that can be economically or safely fed per day is probably between 2 and 4 pounds.

COMPOSITION OF COCOA SHELLS.

This is a waste or by-product from the cocoa and chocolate factory. A sample received from Halifax, N.S., with a request for a report on its feeding value, furnished the following data :—

	Per cent.
Moisture	5·12
Albuminoids (flesh formers)	16·44
Fat	12·92
Carbohydrates—sugar, etc	45·43
Fibre	13·17
Ash or mineral matter	6·92

FERTILIZING CONSTITUENTS.

Nitrogen	2·63
Phosphoric acid	·98
Potash	2·59

The analysis makes clear that it contains a high percentage of albuminoids, and is also rich in fat—two of the most important constituents of a feeding stuff. Providing it is fairly digestible, a point upon which we have no information, save that cocoa butter or fat is readily assimilated,—this refuse material is a concentrated feed of high order. If ground to the condition of a fine meal, I am of the opinion that its digestibility would be much increased, and that it would prove serviceable as furnishing a part of the concentrated portion of the ration.

The quantity that could safely or profitably be fed per diem would have to be ascertained by actual experiment; probably about 2 pounds a day, with other meal, would be the limit. Again, it is not known whether it would impart any flavour to the milk or butter produced, but we should not expect to find any, if used in the amount already indicated.

Attention is directed to the richness of this material in fertilizing constituents, more especially nitrogen and potash. These, for the most part, would be recovered in the solid and liquid excreta of the animals to which it was fed.

SUGAR BEETS.

At the request of the Department of Agriculture of British Columbia, a chemical analysis has been made of certain samples of sugar beets grown in that province. The beets, comprising 17 samples, were received during December, 1897 and January, 1898. Nearly all the roots had sprouted, and consequently had deteriorated as regards sugar content.

Many of the roots were too large for the sugar factory; from 1 pound to 2 pounds is the weight sought by experienced growers. Beets heavier than this are invariably low in sugar. Again, many of the beets were forked and irregular in shape, showing a poor tilth and probably a hardy and stony condition of the soil. Such roots are not liked at the factory, as they entail a considerable waste of material.

The following data are furnished by Mr. J. R. Anderson, Deputy Minister of Agriculture, Victoria, regarding the beets. The seed had been supplied to the grower by the Department of Agriculture for British Columbia :—

PARTICULARS *re* SUGAR BEET SAMPLES SENT FOR ANALYSIS.

Number.	Name of Grower.	Locality where grown.	Nature of Soil.	Culture.
1	W. le Poer Trench	North Saanich		
2	S. Knight	Popcum		
3	R. McBride	Sea Island		
4	D. Rowan	Lulu Island	Clay loam	Planted May 18, lifted Nov. 13; 18 ins. between rows, 10 ins. between plants.
5	H. T. Thrift	Hall's Prairie	Black bottom soil; heavy clay subsoil.	Planted May 12, lifted Nov. 9; 18 ins. between rows, 10 ins. between plants.
6	J. A. Catherwood	Mission	Dark sandy loam soil (a year previous was "alder bottom").	Planted May 24, lifted Nov. 13.
7	W. J. Harris	Pitt Meadows	Clay loam	Planted May 24, lifted Oct. 20; 2 ft. between rows.
8	G. H. Hadwen	Quamichan		
9	R. H. Breeds	North Saanich		
10	T. W. Graham	Shuswap	Loam with clay bottom	Planted May 16, lifted Oct. 3; drilled 26 ins. apart.
11	G. Hutcherson	Delta		Rows 12 ins. apart.
12	J. T. McIlmoyl	North Saanich		
13	H. V. Baker	Cranbrook	Heavy loam	Planted middle June, lifted end of Aug.; 18 ins. between rows and plants.
14	A. C. Wells & Son	Chilliwack	Clay loam	Planted May 14, lifted Nov. 4; 2 ft. between rows, 9 ins. between plants.
15	H. F. Page	Matsqui	Sandy loam	Planted July 1, lifted Nov. 10; 18 ins. between rows, 9 ins. between plants.
16	Thos. Kidd	Lulu Island	Alluvial loam	Planted May 26, lifted 1st week in Nov.; 18 ins. between rows, 8 ins. between plants.
17	J. M. Manley	Agassiz	Sandy; some little clay mould.	Planted May 25, lifted Nov. 1; 2 ft. between rows, 6 ins. between plants.

The value of beets for the manufacture of sugar depends upon their richness in sugar and the purity of their juice (coefficient of purity). To obtain beets with a high sugar content and pure juice, it is not only necessary to procure sow seed from tested roots or varieties of acknowledged richness, but also to pay great attention in the selection and preparation of the soil and the subsequent culture of the beets. For information on this subject the reader is referred to pages 132, 133 of the Report of the Farms for 1890.

The results of our examination have been prepared in tabular form, as follows:—

ANALYSES OF SUGAR BEETS FROM BRITISH COLUMBIA, 1897.

No.	Percentage of Sugar in Juice.	Percentage of Solids in Juice.	Co-efficient of Purity.	Average Weight of one Root. Lbs.	Oz.	Remarks.
1	15·1	18·0	83·9	1	8	Medium size, regular, good shape.
2	11·4	15·4	74·0	2	3	All sprouted " "
3	11·8	16·3	72·4	3	0	Too large, all sprouted "
4	10·4	15·2	68·4	3	5	" " much forked.
5	14·8	18·3	80·9	2	9	" " some roots forked.
6	15·3	18·2	88·2	0	9	All sprouted, of good shape and regular.
7	11·0	14·1	78·3	0	12	Very much sprouted.
8	11·9	16·2	73·8	1	15	Regular, not sprouted.
9	14·7	17·8	82·8	1	9	Several roots sprouted, fair shape and size.
10	12·5	16·5	76·0	3	1	All sprouted, good shape, but too large.
11	15·0	18·0	83·3	1	6	All somewhat sprouted, forked.
12	13·2	18·2	72·5	3	12	" " too large, several forked.
13	16·0	21·7	73·9	1	6	" " good size, but forked.
14	12·2	16·9	76·4	3	12	" " good shape, not forked, too large.
15	13·0	18·4	70·7	1	12	" " good size, but irregular.
16	13·5	18·5	73·0	1	1	Not sprouted, regular, good size and shape.
17	14·2	18·6	76·3	0	13	Good size and shape.

These figures do not indicate, in the majority of instances, either a rich or pure juice, but as many of the roots had not received any special culture and were badly sprouted, they must not be regarded as demonstrating the possibilities of British Columbia in producing beets profitable for sugar extraction. There is no reason to suppose there are any conditions of soil or climate in British Columbia inimical to the production of rich beets with a high percentage of sugar.

CANADIAN AND HUNGARIAN FLOURS.

At the request of the Hon. Minister of Agriculture, the following critical study of samples of Canadian and Hungarian flours was made. The flours selected were "Best Patent," Lake of the Woods Milling Co., and "5-Star best grade E.O.P.O. Hungarian."

ANALYSIS OF FLOURS.

——	Best Patents. Lake of the Woods Milling Co.	5-Star Best grade. E. O. P. O. Hungarian.
Moisture	11·47	11·51
Albuminoids	12·59	11·27
Fat or oil	1·82	1·87
Ash or mineral matter	·37	·34
Wet gluten	34·22	26·17
Dry gluten	12·33	9·79
Ratio of "dry" to "wet" gluten	2·77	2·67

Moisture.—The percentages obtained are so close that the flours, as regards this constituent, may be considered as practically identical.

Total Albuminoids or Protein :—The percentages of total albuminoids—the most important constituent of flour from a nutritive standpoint—have been obtained by the usual method, the multiplication of the percentages of nitrogen (directly estimated) by 6·25.

The present results show the Canadian flour to be much the richer of the two (approximately, 10 per cent calculated on the albuminoid content) in these nitrogenous substances, of which the special function in the animal economy is the formation and repair of the principal tissues of the body.

Fat and Ash.—As in the case of the moisture, the data representing these two constituents in the two samples differ so little that special comment as to the relative percentages is unnecessary.

Gluten—Wet and Dry.—Though not of the same accurate nature as the foregoing analytical data, the determinations recorded under these headings are exceeding useful as indicating the relative "strengths" of the flours. The term *strength*, as used by millers and bakers, denotes, chiefly, the bread yield, which is largely dependant upon the power of a flour to absorb and retain water ; it also includes, however, "capacity of a flour for producing a well-risen loaf", that is, it takes into consideration other physical properties besides that above mentioned—qualities usually concomitant with the absorbent ratio.

The weights of moist and dry gluten from the Lake of the Woods flour exceeded those from the Hungarian sample. If the amounts of moist and dry gluten in the former be each represented by 100, then 77 and 79 will represent the moist and dry gluten, respectively, in the latter. We may therefore, conclude as regards yield of bread from a given weight of flour, that the Canadian brand is far superior. The "falling off" in the oven would be somewhat similar for both flours.

Respecting the *quality* of the gluten, that prepared from the Lake of the Woods sample was found to be firm, tough and elastic ; indeed, as far as one could judge, these properties—so valuable in bread-making—were more marked in the gluten from the Canadian flour than that from the Hungarian flour.

The chemical data, strength and gluten estimations, in our opinion, all point to the superiority of the Canadian flour for bread-making purposes.

CANADIAN SOILS.

But very few soils have been submitted during the past year to complete analysis, owing to the large amount of other and more pressing work. There now awaits examination a considerable number of samples of virgin soils, which will be taken in hand and reported upon as opportunity permits. Certain samples have received a preliminary or partial analysis, and suggestions as to the treatment of these soils drawn from the results obtained, have been furnished to the interested parties. A few of the more important of these reports are here inserted, in the belief that they will furnish useful information to many of our readers.

From Grindstone Island, Magdalen Islands, Que. Two soils, the one a virgin soil ; the other, cultivated for some years, but never manured, were forwarded by Mr. A. S. D. Van Barnveldt, estate agent and representative, Grindstone Island, who is anxious to establish agriculture among the fishermen there. He requested that the analysis be accompanied by suggestions for economically increasing the fertility of the soil and the most profitable chemical fertilizers to apply. Both samples show the red colour so

characteristic of the soils of Prince Edward Island. They are light, sandy loams, full of small pieces of the sandstone which has formed the basis of the soils. The fine soil, separated by sifting, was submitted to analysis, with the following results:

A. Cultivated, but never manured; had grown oats and hay for several years.

B. Virgin soil—unmanured and uncultivated.

ANALYSIS OF SOILS FROM GRINDSTONE ISLAND, MAGDALEN ISLANDS, QUE.

Constituents.	"A" Cultivated soil	"B" Virgin soil.
Moisture	2·49	3·14
Loss on ignition (organic matter)	6·31	9·79
Insoluble residue (clay and sand)	81·13	77·04
Oxide of iron and alumina	8·85	8·90
Lime	·17	·25
Magnesia	·97	1·33
Potash	·14	·19
Phosphoric acid	·22	·24
Soluble silica	·05	·05
	100·33	100·93
Nitrogen	·162	·189

Though these soils, as regards chemical composition and texture, must be considered below the average, they are by no means wanting in the elements of fertility, and their improvement might be undertaken with a fair hope of success, providing the climatic conditions for crop production are not unfavourable.

First, we would advocate the addition of organic matter. This would be especially valuable in making the soil more firm and compact and more retentive of moisture, warmth and plant food. The further decay of such organic matter within the soil would assist in liberating mineral plant food in an available condition. Barn-yard manure, of course supplies organic matter in large quantities, but as I understand there is not an adequate supply of this material on the Island, the use of such naturally occurring fertilizers and by-products as sea-weed and fish offal, both of which contain other elements of fertility in large proportions—the former being rich in potash, the latter, in phosphoric acid—is to be strongly advised. Further, the growth of clover or some other of the legumes would be most beneficial. The turning under of such a crop would not only enrich the soil in humus and available potash and phosphoric acid, but would also increase its percentage of nitrogen. The extensive growth of clover is sure to be followed with good results. It may be sown with all grain crops, the clover being ploughed under as late in the season as the weather allows, or in the following spring. It would also, no doubt, be an economical method to sow clover expressly for the purpose of turning under. This so-called "green manuring" is perhaps the most profitable and permanent method for the enrichment of such soils that could be recommended. To induce a good growth of clover, the soil should receive an application of potash and lime. Wood ashes, kainit, or muriate of potash would supply the former; lime, marl, or gypsum, the latter. If wood-ashes are used, there would be no necessity to add lime or any of its compounds, since they contain about 30 per cent of lime.

These soils are especially poor in lime, and consequently a dressing of lime (20-40 bushels per acre), or gypsum (say, 200 to 500 pounds per acre) would be most advantageous. Nitrogen and phosphoric acid would be furnished by fish offal, of which I suppose there is a more or less ample supply on the islands.

Respecting commercial fertilizers, I would say that their use should only be supplemental to the treatment already outlined. These soils are leachy and must be made more retentive before the greatest good can be expected from the use of soluble plant food as is supplied by chemical fertilizers.

If organic matter and nitrogen can be furnished in the way indicated, and phosphoric acid and potash added by means of fish waste and sea-weed, the further improvement by potash salts, superphosphate, or Thomas slag (for phosphoric acid) and nitrate of soda, will be accompanied with profit. It is impossible to state exactly the amounts of these materials that will give the best results, but the following quantities will serve as a guide. The character of the crop to be grown will necessarily determine this to a large extent :—

Superphosphate	300 lbs. per acre.
or	
Thomas basic slag	300-500 lbs. "
Kainit	200-400 lbs. "

to be harrowed in after autum ploughing.

After growth has appeared in the spring, broadcast 50 pounds of nitrate of soda per acre, to be followed by another dressing of 50 pounds some three weeks or a month later.

In the treatment of light soils, such as we are now considering, it is always better to apply manures and fertilizers in moderate quantities annually, than large dressings at less frequent intervals.

In comparing the analytical data of the two soils, the exhaustive effect of the cropping without replacing the plant food is quite apparent. In all the principal constituents that go to make up soil fertility-humus, nitrogen, potash, lime, and phosphoric acid—the virgin soil (b) shows much larger amounts. These facts teach a lesson that should not be neglected, for under the present onesided method of farming it will not be long before the store of plant food in the soil is so reduced that crops cannot be profitably grown.

From Pefferlaw, Ont.—Forwarded by Thos. Corner : A grayish black, sandy loam of a very loose texture. From appearance, it would be judged as warm and responsive, but light and apt to dry out quickly.

ANALYSIS OF SOIL (AIR DRIED.)

	Per cent.
Moisture	1·99
Organic and volatile matter	9·62
Mineral matter, soluble in acid, chiefly oxide of iron	5·76
" insoluble in acid, chiefly sand	82·63
	100·00

Lime ...... Very small quantity.

	Per cent.
Nitrogen	..·264
Sand (approximately)	78·00
Clay, organic matter, &c. (approximately)	22·00

For a sandy soil it may be accounted rich in organic matter and nitrogen, though it is doubtful if any large percentage of the latter is in a condition immediately available as plant food.

In mineral constituents, save iron and alumina, it is poor, and therefore fertilizers supplying phosphoric acid, potash and lime, as well as available nitrogen, should be employed.

In recommending a fertilizer for onions, especially asked for by one correspondent, on this soil, we would point out that if any way possible, the land should have a coating of well-rotted barn-yard manure, poultry manure or rich compost. As it is stated that wood ashes are not obtainable, the following fertilizer would probably be most economical and profitable to use:—

Superphosphate	250 pounds per acre.
Muriate of potash	200 " "
Nitrate of soda	150 " "

Apply the superphosphate and muriate of potash in the autumn, if possible, lightly ploughing or harrowing under the mixture. Apply the nitrate of soda broadcast in, say, three top dressings, the first being given soon after the growth of the young plants has begun. The second and third applications may be made at intervals of three weeks.

From Township of Nepean, near Ottawa, Ont.—Forwarded by Mr. Hugh Hinds: A grayish red, sandy loam, and would be termed a very light soil.

ANALYSIS OF SOIL (air-dried).

	Per cent.
Moisture	1·31
Organic and volatile matter	5·63
Mineral matter, soluble in acid, chiefly oxide of iron	6·45
" insoluble in acid, chiefly sand	86·61
	100·00

Lime.................Only present in traces.

	Per cent.
Nitrogen	·154
Sand (approximately)	86·00
Clay, organic matter, &c. (approximately)	14·0

For a soil of this character, it would not be considered deficient in organic matter and nitrogen, though both of these must be greatly increased, either by stable manure or ploughing under green clover or peas, if the best results are to be expected. The soil would also respond to liberal applications of lime, phosphoric acid and potash. It also stands in need of lime.

To furnish the soil quickly with humus (vegetable matter) and nitrogen, no better material than stable manure—and the soil would easily stand 20-30 tons per acre—could be advised. If wood ashes can be readily obtained, they will probably be the cheapest form of potash available. They also furnish phosphoric acid and lime. For potatoes, vegetables and fruit trees, use from 50 to 100 bushels per acre, lightly ploughed or harrowed under as early in the season as possible.

During the early weeks of growth, give a top dressing (broadcast) of nitrate of soda, for vegetables, and if it can be afforded, for all crops, save the larger fruit trees. It is well to apply this fertilizer in two dressings, a few weeks apart, using about 50 to 60 pounds per acre at each application.

From near Port Arthur, Ont.—A yellowish-red sandy loam, and, from appearance, as well as from the analytical results, would be considered a light soil, somewhat below average fertility:—

ANALYSIS OF SOIL (air-dried).

Moisture	1·58
Organic and volatile matter	4·48
Mineral matter, soluble in acid, chiefly oxide of iron	15·01
Mineral matter, insoluble in acid, chiefly sand	78·93
	100·00

Lime	only present in traces.
Nitrogen	·075
Sand (approximately)	30·8
Clay, organic matter, &c. (approximately)	19·2

Its chief deficiencies are humus and nitrogen, though in the mineral constituents of plant food it might also be enriched to advantage. Lime is present only in traces, so that an application of marl, gypsum or lime in any form would undoubtedly give a profitable return. If wood-ashes were cheaply obtainable, we could not advise a more economical mineral fertilizer, for they supply potash, phosphoric acid and lime—all of which would increase the fertility of the soil. Instead of wood-ashes, a mixture of superphosphate kainit (the latter contains about 12 per cent of potash) may be used.

Regarding humus (vegetable matter), barn-yard manure, of course, would be most valuable, but as the supply of this material is no doubt limited the deficiency can be made good by the growing of clover alone or with grain crops. In this connection, it is gratifying to learn that this soil will grow good crops of clover. This is due, probably, to the potash, resulting from the ashes of the fire that passed over the district some years ago.

If there are any deposits of muck in the district, the farmers should be advised to utilize them. After digging and piling the muck it should be allowed to weather and air-dry by exposure. It will then form an excellent absorbent to use about the farm buildings and in the barn-yard. In this way much valuable liquid manure will be saved and the inert plant food in the muck rendered available. The resulting manure will prove most valuable to soils of this character.

Being a light soil, it would not be advisable to plough too deeply, but where there is a sub soil of clay within easy reach of the plough I should advise a judicious admixture with the surface soil.

This soil appears to be very similar to a sample sent by Mr. Wm. Wilson, from about six miles west of Port Arthur, the analysis of which appears in the Farm report for 1894. Unfortunately, this sample was destroyed in our disastrous fire in 1896, so that no comparison can be made as to the appearance of these two soils.

FERTILIZERS.

SWAMP MUCK.

From the correspondence and the number of samples of this material received for examination during the past year from farmers in the Dominion, it is evident that the testimony given in former reports of this Division regarding the value of this naturally-occurring fertilizer has attracted attention to many of the muck deposits of Canada. Since, however, we have in previous years devoted considerable time to the analysis of swamp mucks, and being much pressed with other work, these samples have not been submitted to a complete chemical examination. Sufficient work in most instances was, however, done to enable the writer to forward a preliminary report to the sender as to the general character and value. As time permits, these samples, or such as are from districts from which samples have not hitherto been sent, will be analysed and the results published in the annual report.

The following table presents the composition of six samples that have been analysed the past year.

ANALYSIS OF SWAMP MUCK (AIR-DRIED), 1898.

No.	Locality.	Sender.	Nitrogen.		Organic and volatile matter.	Sand and clay.	Mineral matter soluble in acid.	Water.
			Per cent.	Pounds in one ton of air-dried material				
				Lbs.

4	Churchill, Ont...........	F. A. Rogerson...	1·04	20·8	40·59	1·70	8·02	49·69
5	Little York, P.E.I........	J. H. Gill........	2·11	42·2	55·84	24·22	8·98	10·96
6	"	"	1·49	29·8	78·91	4·22	4·88	11·99

Nos. 1, 2 & 3.—It will be noticed that the chief differences between the samples lie in the proportion of vegetable and mineral matter, and that as the organic matter decreases, so does the nitrogen. Since this latter element is the one of greatest importance in mucks, the samples receive their value in the order given. All three specimens would make fair absorbents and prove useful for composting purposes.

No. 4.—A very fair sample. If further allowed to dry by exposure it would make an excellent composting material.

Nos. 5 & 6.—Usually, the amount of vegetable matter is a measure of the nitrogen present; such, however, in this instance is not the case; that with the largest amount of organic matter contains the least nitrogen, and *vice versa.*

Although swamp muck contains considerable quantities of plant food—and especially of nitrogen—we would remind farmers that this plant food needs preparation before it can be of any service to growing crops. By exposure in the pile, the muck is "weathered" and dried. It is then in a excellent condition to use in conjunction with litter in the cow-house, pig-pen, &c., indeed, everywhere about the farm buildings where

there is liquid manure to absorb and retain. It will also prove a valuable addition to the manure heap, keeping the mass moist, and thus controlling fermentation. When thus further decomposed by rottting manure, the manurial value of the muck is much increased.

For a more detailed account of the methods of treatment and uses of muck the reader is referred to reports of the Division of Chemistry for 1896.

BASIC SLAG: THOMAS' PHOSPHATE.

This comparatively new phosphatic fertilizer is now extensively advertised in Canada, and consequently many inquiries have been received regarding its nature, composition, value, etc. To furnish this information the following short article has been written:—

In the manufacture of steel by the Bessemer process a slag is formed rich in phosphoric acid. It is, in fact, chiefly, basic phosphate of lime. This by-product (it was until recently also a waste product) produced by the union of the phosphorus of the iron with the lime of the flux employed, is reduced to a fine powder and put upon the market as an agricultural source of phosphoric acid under the name of Gilchrist Thomas' Slag, Basic Slag, Thomas' Phosphate, etc. Without any further treatment it is applied to the soil.

Basic Slag contains from 15 to 20 per cent of phosphoric acid. In the Report on Fertilizers by the Department of Inland Revenue (Bull. 55), March, 1898, analysis of two samples are given, as follows:—

Basic or Thomas Slag.	No. 820.	No. 848.
Total phosphoric acid	16·76	16·25
Total available phosphoric acid	5·93	7·80

It also possesses a certain amount of free lime.

As regards the availability of its phosphoric acid it may be said to rank next to superphosphate, for though not immediately soluble in water, it is readily soluble in dilute acids. For this reason we may suppose it to be easily acted upon by the exudations of rootlets and absorbed.

Many agricultural chemists place the phosphoric acid in Basic Slag on a par with the "reverted" phosphoric acid in superphosphate. Extensive experiments in Germany by Wagner and others have established its value for all crops requiring phosphoric acid; this value is approximately estimated at one-half that of superphosphate. Wagner recommends for ordinary crops an application of 500 pounds per acre.

It should always be bought on analysis, and since its usefulness depends upon its fineness, farmers should see that they buy only that which is in the form of an impalpable powder.

It can be used in mixtures with nitrate of soda and the German potash salts without detriment, but should not be previously mixed with sulphate of ammonia, as such would result in the loss of valuable nitrogen.

Basic Slag responds best on peaty soils, soils that are sour through insufficient drainage, soils rich in humus and those deficient in lime.

SOUTH CAROLINA ROCK.

This is another phosphatic fertilizer that has found its way on to Canadian markets, though as yet it has not received an extensive trial in the Dominion.

"Phosphate Rock" occurs naturally and in vast deposits in North and South Carolina, Florida and Georgia. Two varieties may be recognized, the so-called "river" and "land" phosphates. The river phosphate is dredged from the beds of rivers or taken from swamps; it varies from gray to black, and contains from 50 to 60 per cent of phosphate of lime. It is usually put upon the market in three grades. The "land" phosphate is of a yellowish colour, and frequently contains large percentages of iron and alumina.

These rock phosphates are ground extremely fine and sold as "floats," to be applied directly to the soil. The finer it is ground the more immediately will be its effect upon the crop. For most crops and under ordinary farming conditions we could scarcely advise the use of this untreated phosphate rock, even if finely ground, since but a very small percentage of its phosphoric acid is soluble, and its action is consequently extremely slow. Treated with sulphuric acid it makes excellent superphosphate—a fertilizer valuable for supplying immediately available phosphoric acid. The phosphoric acid in phosphate rock is rated at about 2c. per pound, making the selling price of material worth about $10.00 per ton.

WELL WATERS FROM FARM HOMESTEADS.

As in former years, a number of waters from farm wells have been examined in the Experimental Farm laboratories. The results obtained have already been reported in full to the senders of the samples, but it has been thought that the insertion in the annual report of the Chemical Division of the analytical data, together with a brief remark as to the purity or otherwise of the waters—as has been customary in the past—would be both useful for reference and valuable from an educational standpoint. In the following table the results of the examinations are given. These waters, received between 30th Nov., 1897, and 1st Dec., 1898, are, as will be seen, from many widely distant points in the Dominion. Of these, thirty per cent have been passed as free from impurity, sixteen per cent have been reported as decidedly suspicious, and fifty-four per cent have been condemned as dangerous to health.

The desirability, or rather the necessity, of pure water, if the health is not to be endangered, must be realized when we remember the very important part that the water we drink and consume in our food plays in the nourishment of the system. The body is made up largely of water, a man, weighing, say, 148 pounds contains about 90 pounds of water. The blood which bathes every tissue and which carries the digested food products to every part for the growth of bone, flesh and brain, and which constitutes about one twelfth of the body weight, is largely water The food is digested and assimilated by the aid of water. The waste products of the vital processes within the body are got rid of largely by means of water. All this water, the water that becomes part of our very selves, is the water we drink or take in our food.

The pollution so commonly found in the water of the farm well is of the nature of drainage from the barn-yard, stable, privy or some similar source, in other words, the contaminated water contains liquid excreta or matter dissolved by the rains from the solid excreta. The danger to the system from this may be considered as two fold. First, it acts as adirect poison. Though probably slow and insidious in its action, it nevertheless has a decidedly injurious effect, lowering the tone of the system, undermining the constitution and rendering it liable to catch any disease that may be prevalent, causing sick headache, nausea, indigestion and many disorders of the intestinal tract. Secondly, such polluted water is a most favourable medium for the growth and multiplication of those germs which are the cause of typhoid fever and other diseases caused by the microscopic organisms. Once such germs find an entrance into the well—and this is generally brought about by drainage from the excreta of patients, as for instance, suffering from typhoid—the water becomes a source of infection.

The well located in the barn-yard or near the privy, really acts as a cesspit. The water, and with it the organic filth in the soil of the vicinity is drawn into the well, since water always seeks its lowest level. This is true no matter how impervious the soil is through which the well is dug—though of course the time elapsing before the well is polluted depends upon the character of the soil and the amount of drainage matter. The number of our farm wells which are true springs, that is, in which water is received from a distant subterranean source, is not large. The common practice, then, of sinking the well about the farm buildings is one that we must strongly condemn, for it is sacrificing, or at all events jeopardizing, health to convenience. It would be much wiser and safer to put the well in the front of the farm-house than at the back, as is now the custom.

We are constantly being asked if such contaminated water cannot be purified and rendered harmless and wholesome. Our reply is that by far the safest plan is to abandon such a well and seek another where there is no danger of infiltration of filth. But until this can be done, the only safeguard is to previously boil all water used in the house. This destroys the poisonous compounds and kills any harmful germs that may be present. The ordinary household filters are practically useless for this purpose. Freshly boiled water is flat and insipid to the palate, but if it is allowed to cool in the open it becomes brisk and pleasant again from re-absorption of air.

The following suggestions and advice are offered to those who are interested in this important subject :—

1. If possible, utilize a spring or pure stream some distance from the farm buildings, and if gravity cannot be used for bringing the water in pipes, a windmill pump or ram, neither of which are expensive affairs now-a-days, should be employed. If, however, it is necessary to sink a well, place it at a sufficient distance from all source of pollution as to be beyond possible contamination. No matter how impervious the soil may appear to be, never sink the well in the barn-yard, under a building

containing animals, or near the privy or the back door. Convenience should be sacrificed, but health should not be jeopardized. Put the well in the front garden rather than in the back yard.

2. Surface and local sewage water should be kept out by lining the well with brick or stone work, laid in cement, to the ground water line. Glazed drain tiles of a foot or so in diameter, cemented together at the joints, make an excellent well, and are not costly.

3. The well should be protected by a closely fitting top, protecting slightly above the level of the ground.

4. The well should be examined and cleaned periodically—frogs, rats, mice, &c., frequently find therein a watery grave.

5. Garbage, household slops, and the like, should never find a resting place near the well. Their proper place is in the compost heap. The habit of throwing both solid and liquid waste outside the back door is both dangerous and wasteful.

6. The well should never be used as a cold storage receptable—accidents will happen. Neither should the milk cans, &c., be washed at the well, unless there is a very efficient drainage therefrom to carry to a safe distance the waste water.

The subject of cleanliness about the farm buildings is intimately connected with that of pure water, as well as that of economy in fertilizing material ; but in this connection I shall only say at present this : that air-dried swamp muck is an excellent absorbent and composting material. Deposits of this naturally-occurring fertilizer are to be found on many farms, and in many localities where such is not the case, it may frequently be obtained for the expense of hauling. It is a material rich in nitrogen, and, therefore, valuable in itself. Its free use in and about farm buildings, where there is liquid manure to be absorbed, will be found profitable, and, at the same time, valuable in keeping the surroundings healthy, and, possibly, the well water pure.

REPORT

OF THE

ENTOMOLOGIST AND BOTANIST

(James Fletcher, LL.D., F.R.S.C., F.L.S.)

1898.

Dr. W. Saunders,
Director, Dominion Experimental Farms,
Ottawa.

Sir,—I have the honour to hand you herewith a report on some of the most important subjects which have been brought officially under my notice during the past season.

As in former years it is, of course, impossible and unnecessary to treat in the annual report of the Division of many subjects which have required attention by the Entomologist and Botanist and his Assistant during the year. The correspondence has increased considerably and is of a varied character; there were 2,771 letters received and 2,906 sent out.

I have had several opportunities of studying important outbreaks of injurious insects and noxious weeds in the field and of attending meetings in widely separated parts of Canada, where it has always been my endeavour to bring prominently before farmers the work which is being done for them in my Division. These occasions have been of inestimable service to me in learning the different conditions prevailing and the methods of farming in vogue in the various parts of the Dominion.

The experiments with grasses and fodder plants have been continued and are always of great interest to visitors. It is satisfactory to be able to record the great success which has attended the extensive introduction of Awnless Brome-grass into the arid regions of the West. Where it has been tried in the East it is also spoken of very highly and is a heavy producer of excellent fodder and hay.

McIver's Rye-grass or Western Rye-grass, a form of *Agropyrum tenerum*, Vasey, found wild in Manitoba and cultivated for some years by the introducer, Mr. K. McIver, of Virden, Man., has given most satisfactory results as a hay and pasture grass. Mr. S. A. Bedford, Superintendent of the Brandon Experimental Farm, who has grown it for many years has always spoken of it in the highest terms. This is also the case with Mr. Angus Mackay, at Indian Head, and with some others who have tried this grass.

Of many mixtures for permanent pastures, grown together under the same circumstances, that known as the Experimental Farm Mixture has again given the best results. This mixture consists of: Timothy, 6 pounds, Meadow Fescue, 4 pounds; Orchard-grass, 2 pounds; Kentucky Blue-grass, 1 pound (where the ground is low, add 1 pound of Red Top); with the above sow the following clovers: Common Red, 1 pound; Mammoth Red, 1 pound; Alsike, 2 pounds; Lucerne, 2 pounds; White Dutch, 2 pounds. The above quantity of seed is for one acre.

Some rather important experiments have been begun along the Ottawa River in the province of Quebec to utilize the swampy lands in places subject to denudation or drowning out during the spring freshets. Mr. C. D. Tylee, of Ste. Thérèse de Blainville,

has been very successful in seeding down some land of this nature which had been broken up and from which the surface soil was carried away or much impoverished by the overflowing of the river in spring.

Another series of experiments is being carried on at the suggestion of Dr. T. Christie, M.P., near Lachute, where there is now a large tract of shifting sand, some five miles in length by about half a mile to one mile in width. The provincial Government of Quebec has encouraged the farmers and assisted them in planting trees. Many of these have done well, and the farmers being all interested are working hard to bring back this tract to what it was only fifty years ago, a beautiful undulating forest land. For the last few years the desert tract has spread very much, the shifting sand drifting over good farm lands and rendering them useless. Several sample packages of seed of the Awnless Brome-grass have been distributed, which it was advised to mix with white clover and sow among the trees. As this land was within quite recent times covered with trees and as all the farmers around it are keenly interested, there is every reason to hope that if all will keep on doing a little every year, planting trees and sowing grass and clover, in time the encroachments of the sand will cease, and the land will be brought back again to usefulness.

Several thousand specimens of plants and insects have been sent in for identification from naturalists in all parts of the Dominion. From these collections several additions have been made to the museum. Many rare and valuable specimens have been added through the kindness of Mr. J. R. Anderson, the Deputy Minister of Agriculture for British Columbia, and from my own collections in British Columbia and the Rocky Mountains during the past summer.

Subjects requiring special attention since I last reported were the following :—

The Rocky Mountain Locust and wheat insects among the enemies of cereal crops; these are treated of fully in this report. Root maggots did much harm throughout the season to cabbages, turnips, radishes and onions.

Of fruit insects, particular mention may be made of the San José Scale and many other scale-insects sent in by correspondents who had noticed them in looking for the San José Scale. The efforts which have been made to control and prevent the spread of the San José Scale, have been so far successful that it may still be said, I believe, that none of our Canadian nurseries are infested, and, as no nursery stock is now allowed to be imported from infested countries, there is every reason to hope that Canada will soon be free from this terrible scourge of the fruit growers to the south of us.

An unusual outbreak was of the Green Fruit-worms on fruit trees in Western Ontario and on maple trees at Niagara, and near Ottawa at Aylmer and Hull, Que.

Tent Caterpillars were enormously abundant in nearly every province of the Dominion, and no important occurrence of parasites was noticed except in British Columbia, where the caterpillars died in large numbers about the time they began to spin their cocoons.

Plant-lice were very destructive to cherries, currants and turnips. This last named attack on turnips was very severe in Manitoba and also in Ontario, where it constituted one of the chief injuries of the year to field crops.

The apples in British Columbia were much injured by the Apple Fruit-miner and by a small moth which has not been much mentioned of late years but which many years ago, under the name of Plum Moth, was described as destructive to plums in Illinois. It also attacked plums as well as apples in British Columbia this year. I have no doubt that the caterpillar of this moth is the one which has frequently been erroneously referred to by British Columbian correspondents as the Codling Moth.

In the province of Quebec a serious and rather remarkable outbreak was by the Plum Curculio in apple orchards at Chateauguay Basin, the fruit being much distorted and rendered unfit for the market.

A few new insect pests must be mentioned :—

In British Columbia the larvæ of an extremely rare longicorn beetle, *Xylocrius Agassizii*, Lec., were imported as borers in the stems of young gooseberry bushes from Oregon. This insect I hope and believe is not likely to become a serious pest.

In New Brunswick the larvæ of a sawfly belonging to the genus *Lyda* occurred abundantly upon raspberries at St. John. There is no mention in literature of a similar attack, but several larvæ are wintering in our breeding jars and it is hoped that the perfect insect will be reared next spring and the species identified.

In Ontario, considerable injury was done in beds of violets, grown by Mr. J. Dunlop, the well known florist, of Toronto, by the larvæ of another sawfly, *Emphytus Canadensis*, Kirby. These false-caterpillars have been complained of occasionally in the past as attacking the foliage of pansies (*Viola tricolor*, varieties), but no great injury by them has been previously recorded.

The Bean Weevil, often mentioned as injuring stored beans in the United States, has this year been found at Strathroy in Ontario.

Meetings attended.—Under the instructions of the Hon. Minister of Agriculture and in accordance with plans made by you as Director, I have taken part in several important meetings during the past year. In January last I attended a convention of fruit growers, nurserymen and official entomologists at Washington, D.C., to discuss the question of legislation with regard to the San José Scale. During the same month, farmers' meetings were attended at Lachute and Cowansville, Que. In February, a series of several meetings was held in New Brunswick in company with Mr. W. W. Hubbard, of Sussex, N.B., and Mr. J. E. Starr, of Nova Scotia, who had just returned from England, where he had been examining into the transit and sale of Canadian fruit. This series ended with a grand convention at Fredericton. On the 24th and 25th of the month meetings were attended in Montreal and at Huntingdon, Que. On May 7th I visited Lachute to examine grass experiments. On June 15th a large farmers' pic-nic was attended at Farrelton, Que. June the 16th and 17th were spent in the Niagara district, driving with Mr. Geo. E. Fisher, the energetic San José Scale Inspector, who has done excellent work in detecting and destroying trees infested with the San José Scale.

On June the 27th I left for the West: the first half of July was spent in the province of Manitoba, holding meetings in company with Mr. Hugh McKellar, the Chief Clerk of the provincial Department of Agriculture. There is probably no one better informed as to the history of the development of Manitoba and its requirements than Mr. McKellar. I, therefore, obtained much valuable information from him with regard to the capabilities of the province. The subjects treated at the several meetings were all in connection with weeds and the legislation relating thereto. The meetings this year were held in parts of the province not visited by us during the two previous years. The subject of weeds is of great interest throughout Manitoba and the Territories. It was a great satisfaction to me to notice a decided improvement in the condition of the farms in this respect since four years ago. This must certainly be credited to the vigorous policy adopted by the Hon. Thomas Greenway, the Minister of Agriculture, and his Deputy, Mr. McKellar. A popular feature of this year's campaign was the establishment of a Weed Tent at the Winnipeg Exhibition, where large bundles of all the weeds of the province were exhibited. This tent was always under the charge of some official from the provincial Department of Agriculture, and I was able myself to be present for the first three days. This exhibit may fairly be said to have been thronged by inquiring farmers who wished to examine the specimens or brought with them weeds to be named and to get advice as to their treatment.

On July the 20th I joined Mr. J. R. Anderson, the Deputy Minister of Agriculture for British Columbia, and travelled with him continuously till August the 8th. Through Mr. Anderson's intimate knowledge of the country, no time was lost and a much larger number of meetings was held than could otherwise have been the case. He being also an enthusiastic botanist, assisted me very much in procuring many valuable specimens of rare plants. By many acts of kindness he added much to the pleasure of my visit.

On my way back to Ottawa, in response to a telegram from the Hon. J. H. Ross, Commissioner of Agriculture for the North-west Territories, I stayed off at Regina, and addressed a meeting of farmers upon weeds and their eradication. This meeting, of which Mr. Gerald Spring-Rice was chairman, was fairly well attended and considerable interest was shown in this important subject.

With the consent of the Hon. Minister of Agriculture, I had the pleasure of preparing for the Hon. J. H. Ross, a Bulletin on the Worst Weeds of the North-west Territories. This bulletin of 29 pages and containing many illustrations, has been widely distributed and has been received with favour by North-west farmers.

While in Manitoba in the beginning of July, and again on 16th August, I had an opportunity of investigating an occurrence of the Rocky Mountain Locust. The outbreak had been referred to in several newspapers, and there was much anxiety among farmers. I was pleased to be able to detect a great many parasites and to explain through the newspapers the true state of affairs; at the same time farmers in the infested district were advised what should be done to avoid a recurrence of the injuries experienced this year.

I returned to Ottawa on 20th August. On the 8th September I attended a meeting at Toronto of the new Canadian Horticultural Society, and delivered an address on fungous diseases and insect pests. The 7th and 8th of November were spent at Lachute and Ste. Thérèse examining the progress of grass experiments, and on the 9th November I attended the annual meeting of the Entomological Society of Ontario in Montreal.

Acknowledgments.—I am under many obligations to kind friends and scientific specialists for much assistance. Mention must first of all be made of my colleagues, Prof. John Macoun, and Mr. W. H. Harrington, of Ottawa, also of Rev. Dr. Bethune of Port Hope, Ont., for valuable help on many occasions, as well as of the following who have extended many courtesies and furnished me with their invaluable publications:—

Dr. L. O. Howard, United States Entomologist, and his staff at Washington, D.C.; Dr. J. B. Smith, of New Brunswick, New Jersey; Professor W. G. Johnson, of College Park, Md.; and Professor T. D. A. Cockerell, of Mesilla Park, N. Mex., for special identification of insects; Professor L. R. Jones, of Burlington, Vt., and Mr. J. Dearness, of London, Ont., for the identification of many plants and fungous diseases. I must again thank my kind friend, Miss E. A. Ormerod, for her continued interest in our work and much valuable advice always freely given.

In conclusion, I beg again to acknowledge the great help I receive continuously in all branches of the work of the Division from my assistant, Mr. J. A. Guignard, B.A.

I have the honour to be, sir,

Your obedient servant,

JAMES FLETCHER,

Entomologist and Botanist.

CEREALS.

The season of 1898 has been a very anxious one for the farmer in Canada. From all quarters correspondents have reported unusual climatic conditions with extremes of heat and drought or low temperatures and heavy rainfall. On the whole, the wheat crop of the Dominion at the end of the season turned out better than could have been anticipated. In British Columbia, with its diverse climates, the small grains gave good returns, particularly on Vancouver Island, in the rich lands along the Fraser River and in the Okanagan Valley. From the North-west the accounts both as to quality and yields are very satisfactory, notwithstanding almost unprecedented rains after the grain was cut. Mr. Angus Mackay, Superintendent of the Experimental Farm at Indian Head, says at the end of September: "From all parts of this district the wheat crop is better than was expected. The lowest yet reported is 28 bushels per acre on stubble land, while many have over 30 bushels per acre. The crops on summer-fallow run from 30 to 45 bushels per acre. There will be an average of from 30 to 35 bushels per acre." In the Manitoba *Crop Report* of August 22, we find: "Perhaps in no year in the history of the province has the productive nature of our soil been so noticeable as the present season. Seeding time was unusually favourable, but for a month or six weeks after seed was sown there was no rainfall. In many fields seed did not even start to grow until late in June, so that, up to the first week in July, prospects were far from promising. A change came during the second week in July, when hot, growing weather gave crops a good start.

"From that time to maturity conditions were favourable. After this, however, another six weeks of cold wet weather set in, from which the wheat suffered considerably. This loss varied much in the different sections of the province, and is variously estimated at from 1 to 33 per cent of the crop. The best reports were from the North-central, South-central and Eastern districts. In the South-west, particularly north of the Turtle Mountains, the crops suffered much from want of rain, and in restricted areas from the ravages of the Rocky Mountain Locust. Some fields never recovered, but others picked up in a most remarkable manner, giving the whole country a strange patchy aspect. The spring drought, followed by rain and growing weather, brought on a copious second growth of grain which, from lack of moisture, had been unable to germinate in the spring."

Mr. Wm. Scott, of the McKay Milling Co., Ottawa, who purchases large quantities of grain both in the Province of Ontario and in the West, says: "The wheat crop this year throughout the Province of Ontario was of exceptional quality, the grain being clean, hard and heavy, some samples grown in the Ottawa valley going 64½ pounds to the bushel. We have received from our correspondents no complaints of attack by weevil or any other insects. The wheat from Manitoba and the Territories is this year of exceptionally good milling quality. The weed question, however, is still one of enormous importance in the Prairie Provinces, and notwithstanding all that has been done, even more effort will have to be put forth by our western farmers in sowing clean seed and weeding their crops, if they hope to maintain their grades of hard wheat and to get the best prices in foreign markets."

In the Ontario *Crop Report* for November, 1898, we find: "Fall wheat: poor yields were exceptional, and large yields were common. The plumpness of the grain is frequently alluded to, in many cases the weight going over the standard and as high sometimes as 63 or 64 pounds to the bushel. Here and there only did correspondents complain of rust, midge or other injury to the crop. The yield is 24 bushels per acre. The acreage of spring wheat is only a little over one-third of that of fall wheat. The crop has been over an average in yield and the quality good."

In the eastern parts of the province of Quebec and through the Maritime Provinces the reports are less statisfactory, rust being frequently complained of; oats, barley,

rye and buckwheat were below the average. The early summer months were very favourable to growth, but the autumn being rainy and foggy had a bad effect on nearly all crops.

"Alberton, P.E.I.—The wheat was very badly rusted, totally ruined in some sections, much damaged everywhere. I never remember a season since I began to make observations when the grains were so universally rusted. The Campbell's White Chaff wheat was being pretty generally sown and this kind suffered most, although no kind was exempt. This was all the more regrettable since the whole crop was so promising. Up to the harvest all went so as to cause us to expect an extraordinary return; such a growth of straw and such fine roots we seldom see; but then came close, damp weather suited to the spread of rust, and the whole province was afflicted with the evil. Besides this we have a short crop of potatoes, and even turnips are not up to the average. The hay crop alone was good, extraordinarily so; but, owing to the great quantities everywhere available, it sells at only half figures. A very moist season like the past advances growth here in this sandy loam of the island wonderfully, if it does not continue too late; if it does, all grain crops are subject to rust. There is this to be remarked, which might well be expected, however, that in these years of blight those who farm intelligently, manure and work well the soil, escape very much better than the makeshift farmers. I would estimate the farm crops of the whole province, as follows: Wheat, a quarter crop; oats, a half crop; potatoes, a half crop; turnips, an under crop; hay, an extra crop."—[Rev. Father Burke.]

"Pleasant Grove, P.E.I., Sept. 9.—All wheat in this section, with the exception of White Russian, is a failure, with rust, maggots or blight. Harvest is about over with us now, all wheat being housed."—[Edward Wyatt.]

WHEAT INSECTS.

It seems strange that there should be so much lack of knowledge and confusion with regard to the few insect enemies of such an important crop as wheat. The different kinds of wheat insects are few in number and unlike in appearance, but there is no crop with regard to which for purposes of exact identification it is so necessary to see specimens of the pests complained of as in the case of wheat. The words weevil, fly, maggot, joint-worm, rust or blight are made to do service for almost any insect or disease which may occur. The chief insect enemies of wheat in Canada in the past have been the Wheat Midge, the Hessian Fly, the Wheat-stem Maggot, the American Frit-fly, the joint-worms, and the Grain Aphis. There are of course some others, such as wireworms, cutworms, and the Wheat-stem Sawfly, which attack the wheat plant occasionally or locally, but the above mentioned are those most frequently inquired about and which, therefore, are of most interest to wheat growers.

With regard to WIREWORMS, which are sometimes the cause of much injury to grain crops, unfortunately it must be acknowledged that up to the present no practical remedy has been discovered. The only agricultural treatments which have proved beneficial are late fall ploughing and sowing infested land to rye or barley which it is claimed that wireworms do not attack badly.

It may be convenient for reference to give a very brief account of each of the worst pests.

THE WHEAT MIDGE or "Weevil" (*Diplosis tritici*, Kirby).—Several small reddish maggots crowding around the grains of wheat in the ear and causing them to shrivel. Some of these when full-grown fall to the ground and pass the winter beneath the surface. Others remain in the ears of wheat and are harvested with the grain. The eggs are laid in June among the flowers of the wheat, being pushed down between the chaff by means of the long slender ovipositors of the females. There is only one brood in a season.

Remedies.—(I.) Burn all rubbish and screenings from the threshing machine. (II.) Plough deeply as soon as the crop is carried.

Formerly this insect was enormously abundant in the older provinces of Canada, so much so that wheat growing was given up in many sections. Of late years the Wheat Midge almost entirely disappeared from Ontario until the present season, and, although mentioned occasionally by correspondents, no specimens were submitted or those sent in proved to be something else. Wheat Midge injury is probably more wide-spread in the Maritime Provinces just now than in any other part of the Dominion. Mr. Wm. O'Brien, of Windsor, Hants Co., N. S., writes: "The wet weather forced the hay and grain to make very rapid growth. But the grain did not appear to fill well, especially wheat and oats. Wheat only about two-thirds filled and very much affected with weevil." At Middle River, Victoria Co., N.S., there was also slight injury by Wheat Midge.

A restricted but severe outbreak of this insect occurred during the summer of 1898 in the Niagara peninsula, Mr. A. T. Small writes:—

"Beamsville (Lincoln Co., Ont.).—I send you a packet of Wheat Midge sifted from one gallon of tailings, some from each of my two neighbours. One of these, Mr. Tufford, a reliable farmer of long experience, who remembers the Midge when it was so bad here 25 or 30 years ago and who has done most of the threshing in this locality, estimates the damage at about 25 per cent. He says that all fall wheat had Midge more or less, Dawson's Golden Chaff and Seneca suffered most. Spring wheat was not affected, but little is grown here. Goose wheat and White Fife were sown last spring."

Mr. Wolston Small, of Ottawa, who spent the summer of 1898 in the Niagara peninsula, saw the Wheat Midge larvæ "so abundant at the time of threshing that the ground beneath fanning mills was quite yellow." He reported the insect as very destructive all along the lake shore in the county of Lincoln.

Fig. 1.—The Hessian Fly—enlarged and natural size.

The Hessian Fly (*Cecidomyia destructor*, Say).—This insect has been at different times the cause of serious injury to the wheat crop of all the older provinces, covering practically the same area as the Wheat Midge. The adult is a very small sooty two-winged mosquito-like fly about $\frac{1}{8}$ of an inch long (Fig. 1). The females lay their minute reddish eggs singly or in clusters on the upper side of the leaf. The young white maggots as soon as hatched work their way down to the bases of the leaves, those of the autumn brood becoming imbedded in the crown of winter wheat, and those of the summer brood at the base of the first or second joint of the stem under the leaf sheaths; there they attack the stem, weakening it so that it very easily breaks down at the point where the injury occurs.

When full-grown the outside skin of the maggots hardens and turns dark brown in colour, when they bear a very close resemblance to small, slender flax seeds, for which reason the pupal stage is frequently spoken of as the "flax seed" stage (Figs. 2 and 3). There are two broods in the season; the flies from the autumn brood which winter over in fall wheat appear in May and June, together with some of the flies from the first summer brood which did not emerge in the autumn; the flies of the autumn brood appear in August and the early part of September. The change from the maggot to

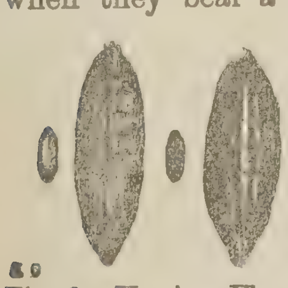

Fig. 2.—Hessian Fly: pupa-cases or "flax seeds"—natural size and enlarged.

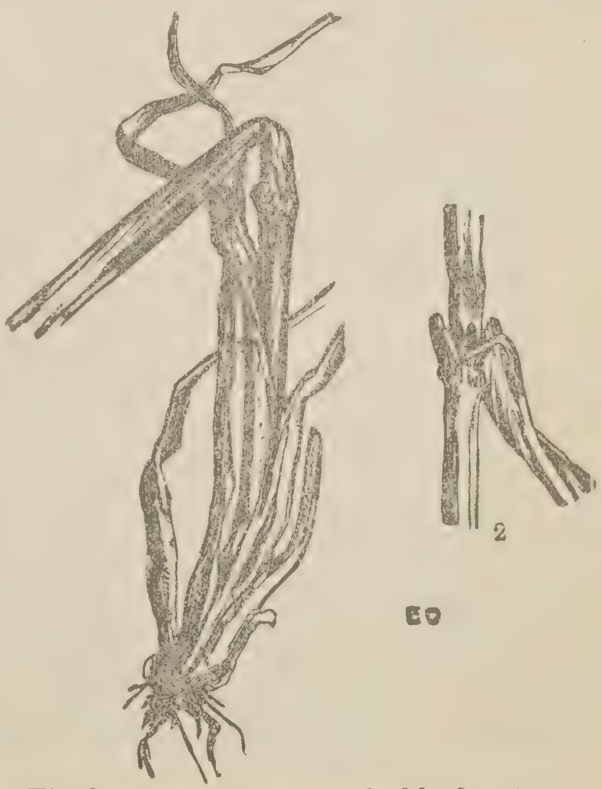

Fig. 3.—Hessian Fly: attacked barley stems: 1, elbowed down; 2, showing "flax seeds."

the pupal condition takes place inside the brown hardened skin of the flax-seed-like pupa-case a short time before the fly emerges.

Remedies.—The remedies most relied on are: (I.) Late sowing. The postponement of seeding until after the third week in September delays the appearance of the young plants above the ground until all the Hessian Flies of the second brood are dead. (II.) Burning refuse. As a large proportion of the "flax seeds" are carried with the straw and at threshing are dislodged and thrown down beneath the machine among the rubbish and broken straw, it is of great importance to destroy all rubbish or screenings wherever it is known that grain has been infested. (III.) Treatment of stubble. As soon as the crop is cut, a harrow should be run over the field so as to start a volunteer crop from the grains which have dropped in harvesting. By the time the fields will require to be ploughed, many flies of the August brood will have emerged and laid their eggs on these plants. The eggs will thus be destroyed at the same time as many seedlings of weeds, when the land is ploughed in the autumn. If fields are conveniently situated away from barns, houses and stacks, much good may be done by burning over the stubbles before ploughing, for the pupæ occur, as a rule, at the first and second lowest joints of the stem. To facilitate burning, a little dry straw may be scattered lightly over the stubble. Should the Hessian Fly ever develop as a serious enemy of wheat in Manitoba and the West, where fall wheat is not grown, burning over and ploughing down of stubbles immediately the crop is cut, will be the best remedies. (IV.) When it is found that a young crop of fall wheat has been injured by the Hessian Fly, it is a good plan to apply the following spring a light dressing of some quick-acting special fertilizer.

The worst attacks by the Hessian Fly which have come under my notice this year have been in Prince Edward Island, and in the province of Ontario in the counties lying between Lake Ontario and Lake Huron. References to injuries by the Hessian Fly in the province of Manitoba were, as far as I could learn, erroneous, although this insect may at some time be expected to appear there also as an injurious species, for Prof. Otto Lugger finds it in Minnesota, in the Red River valley, where the conditions are similar to those of a large part of Manitoba, he says: "A large area is infested, especially the western part of Central Minnesota from Brown's Valley to the Mississippi River at St. Cloud. Further north and south the fly is found in lesser numbers, and only a few occur in the northern part of the Red River valley and along the Iowa State line. The damages in some places amounted to more than 25 per cent, in others to 5 per cent and less, but on an average our farmers lost from 5 to 10 per cent of their entire wheat crop." (Otto Lugger, *2nd Ann. Rpt.*, 1896.)

"Pleasant Grove, P.E.I., Sept. 9:—I send you two samples of infested straw, one from my own field and the other from my neighbour's, which fell down badly this year. There were only a few plants in my field which fell down this season. Since learning from your reports the history of these pests, I have grown good crops of wheat by sowing late and dressing the land with a coat of good manure. My crop this year is a good one, the straw is as yellow as gold and almost free from rust."—[Edward Wyatt.]

Mr. Wyatt kindly supplied me with several samples of infested wheat straws and also with many stems of grasses from a field which had been badly attacked by Hessian Fly. Among these it may be mentioned that two stems of Timothy grass (*Phleum pratense*, L.) contained undoubted puparia of the Hessian fly. This was a matter of considerable interest to me because from the statement made in Miss Ormerod's well-known *Manual of Injurious Insects* I have frequently endeavoured to find traces of the Hessian Fly in any of the wild grasses. The statement referred to (quoted from Dr. C. Lindemann, of Moscow, Russia) is as follows: "Two kinds of wild grasses subject to the attacks of Hessian Fly are Timothy grass and Couch grass. In 1887 the first named of these was found to be severely attacked in the Russian Government of Tambov, and Couch grass was attacked in the Government of Tambov and also of Woronetz; Couch grass was so severely attacked that in whole districts covered with this grass, it was destroyed." This statement is of interest because of its possible bearing on the question of the original home of the Hessian Fly. A species which attacked a wild grass so severely as

above mentioned would appear to be much more at home than where it attacked only a cultivated plant of exotic origin, such as wheat is in America.

From Mr. Wyatt's observations it would appear as though at least two or three different kinds of insects were attacking the wheat on Prince Edward Island.

Samples of Hessian fly were received from several other places on Prince Edward Island. One sample, which came through Mr. F. G. Nash, of the Charlottetown *Patriot*, and was taken from a field of wheat on the farm of Mr. Joseph Wise, was found to be very much parasitized by minute hymenopterous enemies.

THE WHEAT-STEM MAGGOT (*Meromyza Americana*, Fitch).—The presence of this insect in a crop of wheat is very easily detected in the summer time when the ears of attacked stems turn white before the rest of the crop ripens. This injury is known under various names in different parts of Canada, such as "white heads," "bald heads," "silver top." If these stems are examined, it will be found that the base of the topmost joint of the stem has been gnawed away by a slender glassy green maggot a quarter of an inch in length, pointed at one end and having black horny mouth parts; to this injury is due the dying of the heads before the grain ripens. In addition to the above, there is another attack on the wheat crop by the same insect, similar to that of the autumn brood of the Hessian Fly, in the root shoots of fall wheat; it also occurs in many kinds of wild grasses. There is besides an intermediate brood which feeds upon grasses and volunteer wheat and barley. The severity of the summer attack in wheat fields seems to vary very much in different years, according to the season. Occasionally the injured stems will constitute as much as 5 per cent of the crop. This was the case nine years ago in Ontario. When full-fed the larva of the brood which attacks the stems works its way up to the upper portion of the sheath and turns to a slightly flattened and very transparent green puparium, from which the fly emerges at the end of July and during August.

Fig. 4.—The Wheat-stem Maggot: *a*, egg; *b*, maggot; *c*, pupa; *d*, fly—all enlarged. (Figure by Prof. H. Garman.)

The perfect insects, of which three distinct broods appear at Ottawa, viz., in the beginning of June, at the end of July, and at the end of September, are active, greenish-yellow flies, one-fifth of an inch in length, with shining green eyes and three dark stripes extending down the back (Fig. 4*d*). The hind thighs are much thickened, and when the fly is at rest the fore part of the body is raised. Very soon after emerging, the sexes pair and the eggs for the next brood are laid. These are snow-white, spindle-shaped, beautifully marked with narrow longitudinal lines, some of which run into each other. These lines are connected with each other by much slighter transverse lines. When looked for, the eggs are easily seen on the upper sides of the leaves, owing to their white colour, although, of course, they are comparatively minute, about $\frac{1}{40}$ of an inch (Fig. 4*a*).

The Wheat-stem Maggot, which, owing to its attack at the roots of wheat, is also called the Wheat-bulb Worm, occurs all through Eastern Canada, and although the adult flies are enormously abundant in meadows and prairies all the way from northern Quebec through the Lake Superior region, Manitoba and the North-west Territories, its attacks in grain fields have not been complained of under its own name until last season, when it was discovered by Mr. George Greig, the Manitoba agent of the *Farmer's Advocate*, that this insect is the cause of a considerable part, at any rate, of the injury to wheat in Manitoba which has of late years attracted so much attention under the name of "dead heads". In company with Mr. Greig, I was able to confirm this observation at several points in the province of Manitoba during the past summer. There were, however, several stems of wheat which showed the "dead heads", in which we could find no injury by the Wheat-stem Maggot. Some of these stems in one locality had been bruised, without being broken down, by hail. In no case could I find any trace of fungus attack. From the observation of Prof. Otto Lugger, it appears that "dead

heads" are also caused by the attacks of a Frit-fly (*Oscinis soror*, Macq.), the maggot of which is described as boring inside the lower portion of the culm. Throughout the province, although many enquiries were made, there were far fewer complaints of "dead heads" this season than last.

Mr. Peter Elder, of Blyth, near Rounthwaite, Man., showed me all through one of his large fields where last year a serious loss occurred from "dead heads," and not a trace was this year to be seem. Mr. A. C. Hawkins, of Swan Lake, Man., cited in my last report, writes: "Sept. 10.—According to promise, I endeavoured to procure specimens of the larva causing damage to wheat, known as 'dead heads'; but the only sign of insect work I found was an empty cocoon a little over $\frac{1}{8}$ of an inch long and yellowish-white in colour. (Undoubtedly of Wheat-stem Maggot.—J.F.) There were very few 'dead heads' in the crop." Mr. George C. Mannix, of Stonewall, who suffered last year, also writes: "I am happy to say there are no 'white heads' in the wheat this year."

References to "dead heads" made by Manitoban farmers all speak of this injury as being a new one, and, judging from the behaviour of the Wheat-stem Maggot in Ontario, and in Manitoba during the past season, I think it may be confidently hoped that this is not going to be a constant source of loss to the wheat farmers of the West. The insect feeds naturally in the grasses of the prairies, to which under ordinary circumstances it will chiefly resort, and I believe that its attacks upon wheat occurring so occasionally are due to climatic conditions which are not likely to occur every year. Moreover, wherever I have collected the mature flies by sweeping the prairie grasses with a collecting net, I have invariably found large numbers of its special parasitic fly, *Cœlinius meromyzæ*, Forbes. Notwithstanding the above, however, Prof. Otto Lugger, of Minnesota, who has also studied it in his State, where in 1895, 1896 and 1897 it was common from the Red River valley to the central part of East Minnesota, says that it threatens to become in the future a serious enemy of their crops of small grain. "In some parts of the State the late sown rye, which had made but little growth during the autumn and which grew slowly in spring, was greatly damaged, in some cases to the extent of one-tenth of the crop. Wheat did not entirely escape, and the plants infested by the insects showed their presence by their small size and general weakly appearance."

Remedies.—(I.) Should the attack of the Wheat-stem Maggot increase seriously and its presence be shown by the "dead heads," certainly much may be done towards reducing the numbers of the next brood by sowing a drill or two of wheat or barley in close proximity to the infested fields. This should be sown as soon as the injury is detected, so that the young plants may be up in time to attract the females for egg laying. After the middle of August these strips should be fed off by sheep or ploughed down. All stubble should be harrowed as soon as possible after the crop is carried, so as to start a volunteer crop, which should be ploughed down early in September. The late sowing of fall wheat, where this crop is grown, could not profitably be delayed long enough to escape the egg-laying period of the last brood.

(II.) The application of special fertilizers as a top dressing when young wheat is known to be attacked, will help injured plants to throw out new stools and overcome to some measure the effects of the attack.

THE AMERICAN FRIT-FLY (*Oscinis carbonaria*, Loew.).—The maggot of this enemy of the wheat is only $\frac{1}{12}$ of an inch in length and yellowish-white in colour. These maggots may be found in autumn destroying the bases of the stems of several kinds of grasses and of fall wheat. They also occur in spring wheat and grasses in June, attacking the young root-shoots close to the ground and either destroying or seriously weakening them. Some eight or ten years ago the American Frit-fly was the cause of extensive and widespread loss in Canadian wheat fields, but since that time hardly a mention of it has been made by correspondents; nor have its attacks been noticed

Fig. 5.—The American Frit-fly—enlarged.

on grain crops at Ottawa. In 1890 this insect was very injurious in Kentucky, and was well worked up by Prof. H. Garman, who published an excellent bulletin thereon under the name *O. variabilis*, Loew. (*Bull. 30, Ky. Ag. Ex. Sn.*) Prof. Garman writes: "I think it very likely that the *Oscinis carbonaria* of Coquillett's notes is the *O. variabilis* observed by you and me in 1890. I never felt quite satisfied with the determination. The flies were abundant here at that time, but have not been seen since." The life history in many particulars agrees with those of the Wheat-stem Maggot and the Hessian Fly, but there is still some uncertainty as to the range of variation in its habits. Such part of the life history as had been worked out up to 1890 is given in the Annual Report of the Experimental Farms for that year. In Prof. Lugger's Second Report, 1896, what is apparently an allied species is described with the important difference of habit that the larva bores inside the stems of wheat causing them to break down, and before that producing the appearance known as "dead heads." This attack was not observed at Ottawa when the American Frit-fly was so abundant, but the family to which this insect belongs is one which is remarkable for the diversity which is found in the feeding habits of the larvæ.

Fig. 6.—The American Frit-fly: pupa-case—enlarged.

Remedies.—The remedies for this insect are the same as those for the Hessian Fly, viz., the late sowing of fall wheat, the harrowing of stubble (or in the West the burning over or ploughing down of stubble), and the application of special fertilizers in spring.

As some of my correspondents have had difficulty in distinguishing between the American Frit-fly, the Hessian Fly and the root-infesting larvæ of the Wheat-stem Maggot, I quote from my annual report of 1890 the chief differences:—

"The three insects are easily distinguishable in all their stages. In the larval or maggot stages, in which they do all their injury to crops, they may be known by the following characters:—

1. *The American Frit-fly*:—Maggot long and slender, yellowish-white with two small but distinct black hook-like jaws. The last division of the body bears two little knob-like processes. Length when full grown $\frac{1}{12}$ of an inch.

2. *The Wheat-stem Maggot*:—This resembles the last named in shape and structure, but is conspicuously different by reason of its clear glassy green colour, and also by its much larger size, $\frac{1}{4}$ of an inch when full grown.

3. *The Hessian Fly*:—This is proportionately much broader than the other two, of a clearer white than the American Frit-fly maggot and nearly always shows a green stripe down the centre. Instead of the two hook-like black jaws which are present in the two previously mentioned maggots, the Hessian Fly larva has a horny forked organ sometimes called the 'breast-bone.' Length when full-grown, $\frac{1}{5}$ of an inch.

"In the chrysalis stages the differences are equally marked:—

1. *The American Frit-fly.*—The pupa-case is shaped as shown above (Fig. 6) and is of a pale chestnut brown.

2. *The Wheat-stem Maggot.*—Changes to a pale translucent pale green pupa-case (Fig. 4*c*).

3. *The Hessian Fly.*—The pupa-cases of this insect are of a deep rich brown, like small flax seeds (Figs. 2 and 3), and it is in this stage that farmers will most easily recognize the Hessian Fly.

"The perfect insects are very unlike. The American Frit-fly is shown at Fig. 5 very much enlarged. The colours are black and yellowish-white. It is a very small insect, large specimens being only $\frac{1}{15}$ of an inch in length. They are extremely active and hard to observe. The fly of the Wheat-stem Maggot is a slender yellowish-green fly $\frac{1}{5}$ of an inch in length, with three dark lines down the back, eyes golden green (Fig. 4*d*). The Hessian Fly is a delicate dusky gnat, well shown in Miss Ormerod's excellent figure where it is represented magnified and enlarged (Fig. 1)."

The JOINT-WORMS (*Isosoma*).—There are probably more species than one belonging to the genus *Isosoma* which attack the wheat plant in Canada. These injuries appear to be of rare occurrence, but have sometimes been serious in certain localities. In 1895 specimens of fall wheat infested by a Joint-worm were received from Meaford, Ont., on the Georgian Bay. This attack, although amounting to 5 per cent of the entire crop in the year named, has not occurred since. The galls made by this insect were almost entirely in the sheaths of the leaves and not in the tissues of the stems. Last year infested straws containing joint-worms were received from Mr. Wm. Welsh, of Verdun (Bruce Co., Ont.). Although from a district less than 100 miles from Meaford, and further, strange to say, although it is the only other report of noticeable injury by joint-worms to wheat which has been reported to me for some years, it would appear from the different nature of the galls which are entirely in the tissues of the stems and not in the leaf sheaths, that this occurrence may be of a different species of joint-worm. Mr. Welsh writes at the end of the season of 1898: "The joint-worm, which was so abundant last year has done little injury this season. I made many examinations for the insect but could find very little damage. In the grain after threshing there were very few of the hard broken pieces such as I sent you last spring. This disappearance, I think, may have been due to the very wet spring and early summer we had." Unfortunately, the exact identity of the Meaford specimens could not be determined; but, through the kind assistance of Mr. Welsh, who has sent several parcels of infested straw from Verdun, large numbers of the flies have been bred. These were chiefly from stubble collected in the spring, April 15, in a clover field, where they had lain on the ground from the time the fall wheat was cut the year before. Specimens of stubble from the same field, but collected in November, 1897, and broken joints from the stems taken from the threshed wheat which had been kept in breeding jars through the winter, failed to produce more than two or three specimens of the perfect insect, whereas the stubble which was left in the field all through the winter gave hundreds of specimens of the gall-former, all the females of which were winged like the males. Besides these there were two kinds of hymenopterous parasites. Specimens of all of these were submitted to Dr. Howard, so as to get an authoritative decision on the species.

Fig. 7.—The Joint-worm: galls on wheat stems—natural size; fly—enlarged.

Dr. Howard reports as follows: "The species is undoubtedly *Isosoma tritici*, Fitch (*nec* Riley). If you will consult my Bulletin 2, Technical Series, page 17, on Phytophagic Eurytominæ, you will find that this is the species called *I. hordei* by Walsh. I think Walsh's specimens also came from Canada. Among the material sent by you after it was mounted I found two species of parasites, viz., *Homoporus chalcidiphagus*, Walsh, and *Eupelmus epicaste*, Walker."

There are so many discrepancies between the descriptions of the galls and their modes of occurrence and with regard to important points in the life histories of the joint-worms that with a view to working out the identity of the different species I shall be pleased to receive specimens from anyone who may find his crops attacked by joint-worms. The galls will somewhat resemble the figure (Fig.7), given herewith or may be as in the case of the Verdun specimens mentioned above, merely hardened and somewhat curved portion in the straws of wheat, barley or rye.

Remedies.—There is only one brood of the joint-worms, and as they pass the winter in the straw, for the most part so near to the ground that a large proportion of the larvæ occur in the stubble left on the fields, they can be largely reduced in numbers by burning over the stubble or by ploughing it down deeply. The broken off hardened

pieces of straw observed in threshing and cleaning should be carefully gathered and burnt. Sometimes, as stated above, there are no galls formed, the presence of the larvæ causing merely slight swellings and the hard thickened condition of the straw. These portions break off in threshing and many are carried through with the grain. The threshed straw should be examined, and if the larvæ are found therein it should be destroyed either by feeding or some other consumption before the ensuing spring.

THE GRAIN APHIS (*Siphonophora avenæ*, Fab.).—The green, yellow, red or blackish plant-lice which are frequently seen upon all the small grains are well known by most farmers. These insects are found in some numbers every year and in occasional seasons increase to such an extent as to cause widespread alarm. Notwithstanding this general increase in numbers, it cannot be said that their attacks have ever materially decreased the wheat crop of the year, for they are invariably accompanied by various parasites which gradually increase in numbers and feed upon the plant-lice until most of them are destroyed. The two most numerous of these parasitic species in Canada are *Aphidius granariaphis*, Cook, and *A. obscuripes*. In addition to these there are always many of the leech-like larvæ of the Breeze-flies, *Syrphidæ*, which crawl about among the colonies of plant-lice and every day destroy large numbers, as they feed entirely upon plant-lice.

The Grain Aphis multiplies with great rapidity and the insects may be found of all sizes and colours all on the plants at the same time. The females bring forth living young continuously and these young lice are in a few days full-grown and themselves begin to propagate in the same way. There are no practical artificial remedies which can be applied on a large scale to fields of grain.

The WHEAT-STEM SAWFLY (*Cephus pygmæus*, L.), treated of at length in my report for 1896, has only been mentioned by one correspondent.

"Buffalo Lake, Moose Jaw, Assa., March 3, 1898.—I send a few heads of wheat such as appeared in one of my fields last year. This field was hailed out in 1896 and having been sown on summer-fallow the straw was burnt as it stood in the spring of 1897. A week or two previous to cutting, I noticed a great many straws and heads like those I enclose scattered loose among the grain, fully 5 per cent of the crop. You will notice that the heads were well developed at the time. Is this the work of the Wheat-stem Sawfly?"—[George S. Tuxford.]

It may be hoped, I believe, that the attacks of this insect upon grain will be only of an intermittent nature, for where the insect was abundant at Souris, in Southern Manitoba, no appearance of it has since occurred. Mr. J. Wenman writes me again this year that he has not heard of nor seen any trace of the insect since 1896. In company with Mr. Angus Mackay, I examined carefully the wheat fields around Indian Head, where I had collected specimens in 1895 and at the date the mature insects should have been flying, but although the standing grain was swept with a collecting net at all times of the day and in several different localities not a single fly could be found.

CUTWORMS in grain.—Occasionally considerable harm is done in grain crops by cutworms. There are several grass-feeding species in this large family which are liable to attack cereal crops. The injuries to Indian corn are well known and can be prevented to a large measure, but when a field of the small grains is attacked the only recourse is to adopt some agricultural treatment founded on the known life-history of the depredator. The exact identity, then, of the species is of importance, so that the life-history, if recorded, may be used as a guide to escape loss. An instance of the value of such information is found in the following correspondence:—

"Carleton Place, Carleton Co., Ont., May 26.—We send a box containing some cutworms. They have destroyed two fields of our oats. What can be done to prevent them from destroying all our crop? Would spreading lime over the field kill them, and how long will it be until they have passed away, so that it will be safe to sow some other grain or to plant corn on the fields where they ate the crop off?"—[J. Yuill & Sons.]

Reply: "Your letter of the 26th inst. containing cutworms from your oat field came to hand, but the cutworms had eaten each other until only one shrivelled up bitten

specimen remained alive. Please send me some more, and if possible in a tin box with plenty of food. There are two kinds of these cutworms much alike, and I cannot, from the specimen I have, tell whether they are of one which matures early, or of the other which does not reach full-growth sometimes till July. In this case exact identification is very important before I can advise you what crop to sow on your land. Corn for ensilage may, I suppose, with you be sown as late as 12th or 14th June, turnips up to 20th June and rape or Hungarian grass up to 1st July. Spreading lime would have no effect whatever on these caterpillars."

"June 2.—We send you another sample of cutworms, as requested, and have cultivated the field again. We are now waiting your answer to know when we shall be safe to sow again. If it would be safe to sow oats soon, we should prefer that crop."—[J. Yuill & Sons.]

Reply: "I am in receipt of your letter of the 2nd inst. as well as the cutworms sent. These are the Glassy Cutworm, the caterpillar of the Devastating Dart Moth (*Hadena devastatrix*, Brace). I have waited a day or two before answering your letter so as to be able to say—what I now believe to be the case—that you can sow oats safely on your land. If you have any convenience for turning chickens or turkeys on to the field for a day before the oats are sown, they would doubtless destroy large numbers of the caterpillars or their chrysalids. I shall be very much obliged to you if you will let me hear from you later in the season what success you obtain from sowing oats on this land so late in the season. You will, I suppose, probably cut them for green feed.

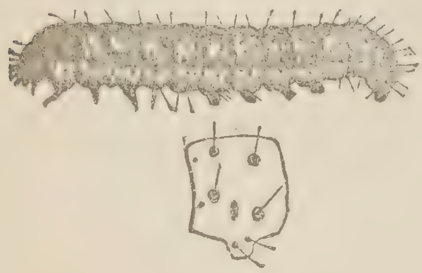

Fig. 8.—The Glassy Cutworm.

"The other cutworm referred to which resembles very much the Glassy Cutworm, but is whiter and has a redder head, is the caterpillar of the Amputating Brocade Moth (*Hadena arctica*, Bdv.), a species which also attacks the roots of grasses and grain. This caterpillar does not reach full-growth usually till after the middle of June."

"Dec. 28.—We broke up about 30 acres of sod land. The autumn before being so dry, we did not get it ploughed. Ten acres of this were sown in peas, the remainder was sown in oats. There were no cutworms in the peas, but all the oats that were sown on sod were eaten more or less. About ten acres was eaten clean out. Following your advice, we turned the turkeys and chickens on the fields and have no doubt but they would have cleaned the cutworms, had it not been that the crows took so many of the young chickens that we were obliged to bring them home.

Fig. 9.—The Glassy Cutworm Moth.

"On the eighth of June we sowed with peas and oats, about 3 parts oats to 1 of peas. This crop was not injured by the cutworms. We had a very heavy crop which we cut a little green and are using for fodder."—[J. Yuill & Sons.]

THE ROCKY MOUNTAIN LOCUST

(*Caloptenus spretus*, Uhler).

It is now some years since any serious injury has been reported in Canada by the Rocky Mountain Locust, although from time to time mention was made in newspapers of the temporary spread up into Southern Manitoba, of small swarms from parts of the Turtle Mountains in North Dakota, where the species breeds probably every year. Such was the case in the autumn of 1897, and the females were seen laying their eggs on the farm of Mr. John Scott, near Deloraine. From these eggs enough young locusts hatched in the spring of 1898 to cause considerable loss in grain crops. The season was

exceptionally dry, and there was no green thing in the country for the young locusts to eat except the settlers' grain crops. The injury of this attack was augmented by the fact that from lack of spring rains a large proportion of the seed grain had failed to germinate, and, consequently, all crops were very thin on the ground.

I visited the infested localities, in company with Mr. Hugh McKellar, Chief Clerk of the Manitoba Department of Agriculture, and drove with him to all the places at which it was known that locusts had been observed. None of the farmers, with the exception of Mr. John Scott, remembered seeing locusts in injurious numbers before. Considerable damage was done on the farms of Mr. J. H. Urie, Messrs. Leonard and Robert Sawyer, Mr. John Scott and Mr. D. S. McLeod. The farm of the last named is at Lennox, the most westerly point visited ; this is just round the spur of the Turtle Mountains from Deloraine. I was unable to visit some farms said to be infested near Boissevain, but through the kindness of Mr. Arthur S. Barton, of the Dingle, Boissevain, and Mr. Charles A. Sankey, of Boissevain, I was kept well informed as to the visitation and provided with specimens for examination. On my return to Ottawa and at the time when the farmers would have finished their harvesting and be at liberty to plough their land, I prepared the following article upon this important subject, and so that it might reach as many farmers as possible, sent it to the *Farmer's Advocate*, which has a very large circulation and which published it both in its Manitoba and its general edition. Similar articles were also published in the *Weekly Star* of Montreal and two or three in the *Winnipeg Free Press.*

THE ROCKY MOUNTAIN LOCUST.

During last June notices appeared in the newspapers that injury was being done by grasshoppers or locusts in southern Manitoba. These reports naturally caused much anxiety among the old settlers who had been in the Prairie Province at the time of the serious locust depredations during 1868, 1870, 1872, and 1874.

Fig. 10.—The Rocky Mountain Locust.

By instruction of the Honourable Sydney Fisher, and at the request of the Hon. Thomas Greenway, I visited the localities reported to be infested in the beginning of July and again in the middle of August. The reports of injuries to growing crops were found to be correct, and the locust which was doing the injury was, as in the former invasions referred to, the Hateful or Rocky Mountain Locust (*Caloptenus spretus*, Uhler).

The exact identification of the species was in this case a matter of no little importance, for it is well known that, although there are many kinds of locusts in the west, none of them are to be feared as crop destroyers to anything like the same extent as the above named, which has exceptional powers of flight and is gregarious in its habits. As is usually the case in such matters, when conviction on this point involved a good deal of extra labour, some farmers were slow to believe that such an ordinary-looking insect could be so serious an enemy as was claimed by those who recognized in the grasshopper of this year their old enemy of the early seventies, and doubts were being cast on the correctness of the identification. This question was at once decided upon catching a few specimens near Deloraine. To one who has studied these insects it is, of course, just as easy to distinguish the Rocky Mountain Locust from its near allies as it is for a farmer to tell wheat from rye, barley or oats.

A good use of this special knowledge was made by Mr. John Scott, who has lived a few miles south of Deloraine for many years. He noticed a swarm of the locusts to alight on his farm last autumn, and this spring warned his neighbours to be on their guard and take some steps to protect their crops, similar to those he himself adopted. As soon as the grasshoppers hatched he spread rows of dry straw across the field where they were most numerous ; the young hoppers gathered into these at night in large

numbers and were destroyed by the straw being set on fire after nightfall. This was repeated four nights running, and myriads were thus killed before they had spread far from their hatching grounds or had done any appreciable harm. Had Mr. Scott's neighbours followed his advice and example, there is no doubt that the loss would have been much less than was the case in that district last summer.

The area over which the Rocky Mountain Locust occurred in Manitoba this year was a narrow strip only a few miles in width, lying to the south of Deloraine and Boissevain, and running along the northern slope of the Turtle Mountains. It is probable that this locust breeds regularly every year in parts of the Turtle Mountains, but it is many years since it spread from these breeding grounds north into Manitoba. It has, however, shown only too well in previous years that it is able to breed and multiply on our prairie lands when once established there. As, therefore, judging from the experience of the last twenty years, it is unlikely that fresh swarms will for some time again spread from their permanent breeding grounds, it is of the utmost importance that everybody in the infested region should do everything possible to help in exterminating this formidable foe. This is particularly the case in the present instance, because if all will work together complete extermination should be a matter of comparative ease. The life habits of the insect are well understood, and the experience of farmers living in regions where it occurs much oftener than with us, shows that by making a very small change in the ordinary methods of working their farms, and at no very large extra expense, this dire enemy can be practically wiped out, even where eggs have been laid in enormous numbers.

WHAT TO DO.

It is conceded by all that the best remedy is the ploughing down of the eggs so deep—five or six inches is sufficient—that when the young locusts hatch in spring they may not be able to work their way up to the surface. The important things, then, for Manitoban farmers to do now are to discover where eggs have been laid on their farms and to see to it that every rod of this land is ploughed either this autumn or next spring before the young locusts emerge and move off into the crops.

WHERE THE EGGS ARE LAID.

The places where the mother insects lay their eggs can be discovered only by seeing them at work, or by examining the soil carefully for the egg-pods. The time required for boring the hole and laying the complement of eggs is three or four hours. The appearance of the insect itself, the pods and the separate eggs are well shown of natural size in Dr. Riley's excellent figure herewith.

Fig. 11.—Locusts laying their eggs.

The female locust lays her eggs in the ground, about an inch beneath the surface, in small pod-like masses, as shown in the figure. The egg-pod consists of a coating of a waterproof mucous material, which is deposited at the same time as the eggs. There are in each pod about 30 eggs, and each female lays about three pods during the autumn. There is only one brood in a season, the winter being passed in the egg. When the young locusts hatch, they emerge through the upper end of the egg-pod. In Manitoba last season the young hoppers were noticed about the 1st of June, but they probably hatched early in May, because it takes seven or eight weeks for the insects to attain full growth, and winged hoppers were abundant by July 8th at Deloraine.

The eggs are laid for the most part in stubble fields. They are very seldom laid in thick sod or in loose, newly-ploughed earth. In the first case it is difficult for the female to form the chamber in which she lays her eggs, owing to the numerous roots of the grasses, and in the second case the burrows could only be made with great difficulty in the dry, powdery earth. All observers report that eggs are rarely laid in newly-ploughed and well-harrowed land.

The late Dr. C. V. Riley wrote: "The egg may be laid in almost any kind of soil, but by preference they are laid in bare sandy places, especially on high dry ground, which is tolerably compact and not loose. . . . Newly ploughed land is not liked, it presents too loose a surface; but new breaking is often filled with eggs." (This is doubtless owing to the firm surface of the sod before backsetting.) "Sandy soil that is compact, especially when having a south or east exposure, is much chosen; but in loose and shifting sand the eggs would perish."

Prof. Otto Lugger, State Entomologist of Minnesota, writing in July, 1889, after examining a district which had been devastated, says as to the places chosen for egg-laying: "A close inspection soon revealed the fact that fields with last year's stubble contained large numbers of eggs, whilst stubble land of the previous year and older contained none or but very few. . . . There were some eggs in denuded spots of timothy fields; . . . where the timothy plants covered the ground entirely no eggs could be detected; a similar observation was made in pastures; if well sodded, no eggs; if bare of vegetation, a few could be detected. No eggs could be found in the native prairie land, and but a few along roads and the elevated beds of railroads."

In the Special Bulletin issued on this subject by the North Dakota Agricultural Experiment Station in 1891, it is stated: "As the eggs are never laid in thick sod nor in loosely ploughed earth, it will be seen that the ploughing need not extend to any land except the stubble fields."

From the foregoing extracts by three of the leading authorities on the subject, it is evident that if farmers will attend carefully to their stubble lands, where by far the greatest proportion of the eggs are laid, there is every hope that next year there may be no trouble from locusts; but, at the same time, it must be borne in mind that unless all help, there were certainly sufficient locusts this year in the district I visited, for the young to commit serious depredations next year, and to spread over a much wider area in the Province.

Remedies.

Ploughing.—The remedy above all others, as stated above, which has given satisfactory results is the ploughing down of the eggs, and although harrowing has been recommended by some, it cannot be relied on. Knowing the importance of giving definite advice to the farmers of southern Manitoba, I corresponded with the State Entomologists of Minnesota and North Dakota, both of whom have had extensive experience in fighting the Rocky Mountain Locust. I submit herewith quotations from recent letters giving most valuable information:

"St. Anthony Park, Minn., August 23.—Ploughing from 4 to 4½ inches deep is the only true remedy. It is not necessary to plough during the fall, though best; if ploughed early in the spring the surface of the field will become quite compact by rain, even by the wind. None or but very few young locusts will reach the surface, and these will starve before reaching plants upon which to feed. Permit no stubble fields. They should all be ploughed, as in them most of the eggs will be deposited. A few acres of stubble land can and will breed enough locusts to endanger the crops of all the surrounding fields. In the past I have repeatedly tried the plan of harrowing in the autumn instead of ploughing, and have invariably failed, since sufficient numbers of locusts hatched to destroy the crop. In fact, the trouble near Perham was almost entirely caused by a party who insisted on harrowing the fields containing eggs instead of ploughing them. He harrowed thoroughly during the autumn, but in spring I found numerous eggs and egg-pods. At my request he harrowed again in spring (would not plough) and seeded with a drill. This field was the principal one in which numerous locusts hatched and from which they migrated to others."—[Prof. Otto Lugger.]

"Agricultural College, N. Dak., Aug. 30.—There is no question as to the efficacy of ploughing. Fields lying side by side on the same ridge of land that were visited by Rocky Mountain Locusts last fall showed this point very clearly. One of the fields was left unploughed, and from this small area probably 250 bushels of grasshoppers hatched out, while in the fields that were ploughed no trace of grasshoppers could be found except as they came from unploughed fields. The farmers in parts of this State find that early fall ploughing gives a much better yield of wheat than either late fall ploughing or spring ploughing, and, for this reason, as well as for the destruction of the locusts, we recommend that all fields in the infested localities be ploughed as early as possible.

"So far as ploughing simply to destroy the eggs of the locusts, there is no reason why this need be done in the fall any more than in the following spring. In fact, in the localities where grasshoppers appeared this year, fields that were ploughed immediately before seeding were as free as those ploughed shortly after harvest, though the ground in both cases was undoubtedly filled with eggs.

"Now, in regard to harrowing, there is no doubt that if the egg masses are brought to the surface and broken at this time of the year the vitality of the eggs will be destroyed. The only question connected with harrowing is how thoroughly the egg-masses will be broken up. Where soil is firm I have recommended harrowing, and then cross-harrowing, so as to disturb every portion of the surface. The disk harrow used for pulverizing sod about five or six weeks after breaking would probably do good work if the ground is too firm for the ordinary harrow. The heavy rains which usually come in August and September here, compact the soil so much that ordinary harrowing would probably fail to serve the purpose. Disking the fields immediately after harvest would leave the soil in such loose condition that the insects would probably avoid that locality for egg-laying."—[Prof. C. B. Waldron, Horticulturist, N. Dak., Agr. Exp. St.]

To secure the best results as far as the destruction of the locusts is concerned, fall ploughing is undoubtedly the most effective method; but, if from press of other work it is impossible to plough all land which was under crop this year, much good may be done by early spring ploughing before the insects hatch or before they are large enough to move from their hatching grounds to adjacent crops. Stubble land which it is intended to summer-fallow next year must be turned down, if possible, before the 1st of June, and at the latest by the middle of that month.

Other Remedies.—Should grasshoppers, notwithstanding all precautions, be found abundant, farmers may have recourse to burning by means of strips of straw, as was done by Mr. Scott this year, or to the use of hopper-dozers or tar pans, which are implements made of sheet-iron, containing some tar or coal oil in the bottom. A cheap and

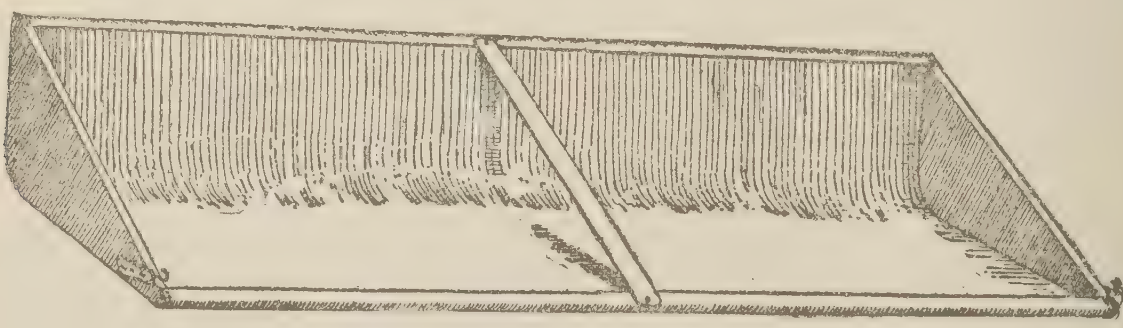

Fig. 12.—Grasshopper Dozer.

simple plan of one of these, costing from $1.50 to $2, was described many years ago by Prof. Riley. It consists of a strip of sheet-iron, 8 or 10 feet long, turned up 1 inch in front and 1 foot behind, with pieces soldered in at the ends (or made of wood) and hooks placed in front at both ends for the attachment of ropes. If to run on rough ground, it will be better to put runners, 1½ or 2 inches high, underneath Into this put a layer of coal tar ½ inch deep, or water and coal oil. The implement can be drawn by a boy at each end, or by a horse if preferred. (*Farmer's Advocate*, Winnipeg, 5 Oct., 1898.)

When examining the insects on Mr. Leonard Sawyer's farm a few miles south of Deloraine, on 8th July, Mr. Sawyer took me to a ravine where he had noticed a great many dead locusts lying among the grass. These were found to have been destroyed by the larvæ of a dipterous parasite. By digging down into the ground beneath the dead locusts, from 1 to 8 of these larvæ could be found, and the dead locusts were so numerous that they lay in every direction among the grass at a distance of only an inch or two from each other. Tachina flies and Flesh-flies were extremely abundant. Upon catching several of the locusts in both the pupal and the perfect stages, by far the larger proportion of them were found to contain the maggots of a fly, and in addition a great many of them were infested with locust mites, *Trombidium locustarum*, Riley. Although many of the maggots of the parasites had buried, none were found which had hardened into brown puparia. This was on 8th July, which may be considered the time when the first brood of maggots leaves the locusts. These latter were just passing the last moult and assuming the winged form. They were hanging in every direction from the stems of grasses, stretching their tissue-paper-like wings by means of their long hind legs. A box was filled with the parasitic maggots and from these were bred (22nd to 26th July), both at Ottawa and by Dr. Scudder, at Boston, large numbers of a flesh-fly which has been named through the kindness of Mr. D. W. Coquillett, of Washington, and pronounced to be "a species of *Sarcophaga* near *incerta*, Walker." They were bred from the living locusts, some of the larvæ being actually taken from insects caught flying in the field.

Dr. Scudder, who kindly furnished me with this identification, also named some other locusts taken at Deloraine among the specimens of *M. spretus*, as *Melanoplus atlanis*, Riley, *M. minor*, Scudd., *Camnula pellucida*, Scudd., and *Gomphocerus* sp.

Efforts were made during the past autumn to discover where eggs were laid and to secure specimens, but all to no avail. Many observers in all the infested localities tried to help me in this matter, but none could find that eggs had been laid. The weather was exceptionally dull and wet. Notwithstanding that no eggs could be found, farmers are earnestly urged to plough all the stubble land that is possible, and endeavour to do this before the middle of June, whether it is to be cropped or summer-fallowed. This matter is one of far too much importance for any one to run the risk of trusting to luck that all will be well, when so much is at stake. Although no eggs have been found, I observed the locusts copulating on 17th August, and large numbers of healthy females with their abdomens well filled with eggs.

I append extracts from letters referring to this outbreak in which most of the points of importance are brought forward :—

"Boissevain, July 9.—I received your letter respecting the locust invasion in southern Manitoba. I have made general inquiries and had extracts from your letter published in local papers. So far, no one has observed any parasitic destruction of the pests ; but that may have been from the fact that, soon after I reported to you, the colony which appeared close to the bush on two farms near here seemed to disperse in a northerly direction. Some were found three miles north of the point where they first appeared. Of course, in this scattered fashion no immediate or general destruction of crops has been observed, but the danger may be all the more serious for another year. I understand that extensive precautions are being taken to the south in the way of deep ploughing, &c."—[Charles A. Sankey.]

"Boissevain, August 14.—I have been unable to discover any number of dead locusts or any of the parasites you asked about. The swarm is now scattered over a distance of a five or six mile radius from the spot where they were first observed, in varying numbers ; we have them here in small quantities. I found one farm, near the bush, where small patches of the wheat heads appeared to have been stripped of the grains, and I discovered a few locusts and a number of several species of ordinary grass-hoppers in the grass surrounding the field. I hope you will discover from your investigations that the danger for next year is, after all, not so great as we fear, but I do trust that if there is any danger you will not minimise it in the least, as farmers are only too ready to put off the thought of an evil day, especially if they can avoid

thereby any present inconvenience or expense. There are a number, however, who are only waiting for your report to take energetic action, should you consider it necessary."—[Arthur S. Barton.]

"Boissevain, September 10.—I have not yet found any eggs of locusts. They are still pairing, and great numbers can be found on the lee side of the wheat stooks. Is there any distinguishing mark on the ground where they lay their eggs?"—[Charles A. Sankey.]

"Deloraine, September 14.—I met Mr. D. Steedsman to-day. He has his man ploughing the ground you advised him to, and the man reported that he had not seen a single grasshopper. Yesterday, Mr. Steedsman himself went with the plough all round the field and did not see a single grasshopper nor any trace of eggs. Per contra I have noticed several hoppers six miles north of Deloraine. There is one point which it may be of importance to mention: during the two weeks preceding Friday, 9th September, we had very unusual weather—cloudy, heavy fogs by night, occasional heavy showers of rain, one especially so on Friday, 2nd September, when for two hours we had a perfect deluge. On Thursday, 8th September, we had a sharp frost, since which the weather has cleared, but to-day (14th September) is again cloudy and threatening rain."—[Dr. Robert S. Thornton.]

"Boissevain, September 24.—"I have not been able to discover any locust eggs as yet, and I have delayed writing in the hope of finding some. There are locusts on nearly every stook of grain. They are still mating, but appear very sluggish, frequently being lifted on to the stack on the sheaf and not attempting to move; this is principally in cloudy weather. I have scraped and dug, and examined (and so have my friends and neighbours), but so far we have not discovered a single egg. Can you tell me, if not too late, if there is any indication or mark left on the surface of the ground that would guide one in looking for the eggs?

"I saw a pretty sight last Friday; a large flock of Black-headed Terns or gulls came swooping down the field; dividing at the leeward side, they ranged the rows of stooks to the other side of the field; returning with the wind in a body, they again and again quartered the field. I was near enough to see them picking the locusts off the stooks as they passed. I came to the conclusion that it was not their first experience, and it would be interesting to learn if their absence this summer was due to locusts further south (in Minnesota), or whether their usual breeding place at Whitewater Lake was too dry for them. In other years we have a constant procession of them backwards and forwards from the lake to the bush, and constantly they follow the plough, picking grubs and larvæ out of the freshly turned furrows."—[Arthur S. Barton.]

"Boissevain, October 22.—I have made a close search for eggs of locusts, but so far with no result. Mr. Barton has also been unsuccessful, though it seems almost incredible to think that none have been laid; apparently a disaster in the shape of a severe snow-storm and frost has destroyed them. I do not think more than one supply of eggs can have been laid."—[Charles A. Sankey.]

"Deloraine, November 14.—With regard to grasshopper eggs: I have not written to you sooner because I had no information to give you. I have scraped and looked on our wheat stubble and on my neighbours' fields and have seen but one female loaded with eggs and no eggs in the ground. I heard of some being found two miles north-east of here and I went there to get some, but I could not find any. Mr. David Steedsman said that they had all moved north from his place and he did not think that there were any eggs laid on his land. Mr. Leonard Sawyer says he saw numbers of small grasshoppers full of eggs. I caught lots of them, and a good many had those worms in them which you showed me when you were here. I do not think many eggs have been laid here, where we had them thickest last year. The grasshoppers seem to have moved north and east and cover more territory than they did last year. While some farmers have ploughed a good deal of land, the fall has been so backward and the harvest prolonged that people have, on the whole, done very little work. I believe we all intended to follow your instructions as much as possible, but now we are frozen up. I heard of eggs being found 8 miles north of Deloraine, through reading your description of them in the *Weekly Star.*

I may find some yet, and if I do will forward them to you without delay. I am very much afraid the province may have more hoppers next year than most people have any idea of. I know that Mr. C. A. Young was trying to get information to send you, but he has nothing definite, so has not written lately."—[John Scott.]

Another outbreak of locusts occurred in the Nicola Valley in British Columbia. This was brought to my notice by Mr. Hewitt Bostock, M.P., who also forwarded specimens for examination.

Reports were also received from Mr. Pooley and Mr. Sidney J. Solomon as follows :—

"Nicola Lake, B.C., September 7.—Yours received *re* grasshoppers. I am sending by this mail some grasshoppers and their eggs, which I hope will be of some use to you in determining the species. The injury done by the hoppers was principally to the ranges and bunch grass pasture fields: also considerable injury to the oats, by their eating off the small stem which connects the grain with straw, and consequently all the oats were lodged on the ground. Injury to wheat, not any; peas, scarcely perceptible. This is the second time the grasshoppers have appeared in our valley. The first time (which was in 1890) they made complete havoc, and unless something happens to destroy the eggs before hatching, it will be very little use putting in a crop next spring. The eggs are deposited on gravel and sandy hills (about an inch below the surface). Some of the eggs seem to have become dried, but the majority are quite fertile. Nearly all the grasshoppers have disappeared and a great many have died."—[William Pooley.]

"Nicola Lake, B.C., Dec. 31.—I could not grow enough feed to keep any quantity of hogs. The grasshoppers were very bad last summer and laid their eggs, so that we are expecting our crops will be all eaten by them next year. I shall put in very little wheat or oats, but principally peas and potatoes, as they do not bother these crops so much."—[Sidney J. Solomon.]

The early disappearance of the locusts mentioned by Mr. Pooley would indicate the probable presence of parasitic insects or some fungous disease. As it was important to know the exact identification of the species which were committing these depredations, the specimens received were forwarded to Dr. Scudder, who reported :—

"Cambridge, Mass., U.S., Dec. 2.—The mass of the material was a species of *Trimerotropis*, probably *cincta*, Thom. Out of the balance, I made out *Camnula pellucida*, Scudd., (many specimens), *Circotettix verruculatus*, Kirby, and *Melanoplus atlanis*, Riley."—[Dr. S. H. Scudder.]

The most numerous species was *Camnula pellucida*, which is sometimes extremely abundant and destructive in the West. This was the case between Kelowna and Vernon, B.C., in 1895.

In the case of this species, undoubtedly the use of hopper-dozers before the locusts have developed their wings would be attended with good results, and if, as is frequently the case with *Camnula pellucida*, the places chosen for egg laying are restricted areas, these may be treated early in June with much less trouble than later.

The poisoned bran remedy recommended for cutworms, page 190, has also been found very effective againts locusts in California.

When the eggs are found to be laid in cultivated ground, the ploughing of this in fall or spring would destroy all the young locusts contained in these eggs, and, if circumstances would permit of it, it might be tried in the Nicola Valley, by placing several small piles of the poisoned bran in the hatching grounds. This material seems to have a wonderful attraction for the locusts.

VEGETABLES AND ROOT CROPS

CUTWORMS.—The complaints of injury to garden vegetables and root crops have been this year fewer than usual, most references to the ordinary garden pests, such as cutworms, Tarnished Plant-bug, plant-lice, etc., being merely to mention their absence. In the province of Quebec, however, there was serious loss in some localities from cutworms, both in gardens and field crops. Very few specimens were submitted for examination, so only general instructions could be given. If correspondents would always send in specimens with their inquiries it would be far easier for the Entomologist and Botanist to give definite information and instructions, and he could thus be of more service to inquirers than is now sometimes the case when no specimens are forwarded.

"Quebec, June 14.—We are receiving from different parts of the province of Quebec letters informing us of the immense damage which is being done to vegetables by the plague of cutworms, against which our farmers do not appear to have any means of protecting themselves."—[S. Sylvestre, Secretary, Dept. Agr.]

"Causapscal, Rimouski Co., 30th May.—I am instructed by the Directors of the Agricultural Circle to send you the accompanying specimens of caterpillars which are occurring here in large numbers and eating up completely our peas, at first the stems and then even the seed pease in the earth. Farmers have been obliged to sow their fields of peas over again. Can you tell us where this pest comes from, how long it will continue to devastate our crops, what it will change to, and above all the best means of destroying it? If we are not able to check this plague, our crop will be a total failure." —[V. O. Morrissette.]

As specimens accompanied this inquiry it was seen at once that they were the so-called Black Army-worm (*Noctua fennica*, Tausch.) and had reached full-growth, so that the application of a remedy was not necessary. These caterpillars were also somewhat abundant in gardens at Ottawa, where they attacked every kind of vegetables, and also to some extent in clover fields. This insect is one which from time to time appears suddenly in large numbers, and then does a good deal of harm. In the last stage of its growth it is a voracious caterpillar which eats indiscriminately almost every kind of vegetation. Prof. Lugger, who treats of it under the name of the Erratic Army-worm, when recording an outbreak which occurred in the State of Minnesota, says that: "The caterpillars devoured every green thing upon the face of the ground. They preferred, however, such plants as were bitter, hence the foliage of cherries, willows, poplars and sumachs was the first to be eaten. After these nearly all others were devoured."

From my own observations of several occurrences of this insect at Ottawa I believe its natural food plants to be the Leguminosæ—cultivated peas and clover being particularly relished. The early maturing of the caterpillars (generally by the end of May or very early in June) frequently prevents the injuries of this insect from being as serious as they might be and actually often seem to be. In 1891 a three-acre field of peas upon the Central Experimental Farm was swept bare by an army of these caterpillars. The damage was stopped promptly by spraying a strip 50 feet wide ahead of the caterpillars with Paris green, one pound in 100 gallons of water, to which 4 pounds of soap had been added to make the solution adhere to the pease. This was applied with knapsack sprayers. Although the pea plants were eaten down entirely on three acres of the field mentioned, owing to the injury being done so early, the plants threw out fresh roots and gave actually a better crop than an equal area in the uninjured portion of the field.

Professor Lugger gives a similar instance in his Second Annual Report, as follows: "Nor was the actual damage done very great, as all the wild plants soon recovered and made a denser growth. The cereals which had been cut down to the very ground, assisted by the moist warm days which followed this invasion, not only recuperated but were in some cases even improved as they stooled better than those not cut by the worms."

The full-grown caterpillar is a handsome creature between $1\frac{1}{2}$ inches and $1\frac{3}{4}$ inches in length, cylindrical in shape, about $\frac{1}{10}$ of an inch in diameter. The general colour being velvety black, with white longitudinal stripes; head, red, black in front; legs, reddish. The dorsal area is more or less shaded with brick red; dorsal stripe of velvety black diamond-shaped marks; the lower edges of the dorsal area clearly defined by a black line, shaded beneath with an equally distinct white thread; sides dull-black, spotted with a few white points which hardly form a line. Spiracles black; sub-stigmatal band distinct, white and undulating, bearing in the centre a very ragged black line washed with yellow, the upper margin dipping below each spiracle and then running up considerably higher than it towards the posterior margin of each segment. Ventral surface semi-translucent, dusky, mottled with white, the green contents of the body showing through the thin skin. When full-grown, about the end of May, the caterpillars burrow rather deeply into the ground and turn to dark brown chrysalids from which the moths emerge about a month or six weeks later. The perfect insect is for a cutworm moth handsome, and all the markings are sharply defined. It expands about $1\frac{1}{2}$ inches across the wings. The upper wings are dark blackish-brown, the orbicular and reniform spots white, bearing a few yellow or reddish scales and outlined with black. In the male the inner margin of the upper wings is yellowish brown, by which this sex can be recognized at once. The lower wings are gray, darker at the margins. There is in Professor Lugger's Second Report a beautiful plate by L. M. Hart, showing the caterpillars, the chrysalis and the perfect moths.

Remedies.—When the Black Army-worm attacks field crops, remedial measures must be taken with due regard to the nature and condition of the crop to be protected. In all instances which I have seen when the caterpillars were abundant enough to march in swarms, it has been possible to forestall them by adopting the well known methods used against the true Army-worm, namely, running a deep furrow in advance of them, burning them in wind-rows of straw, or poisoning them by spraying a strip of the vegetation before they reach it, with a strong poisonous mixture. In gardens, they may be advantageously combated by the same methods used against other cutworms. Owing to their large size at the time when garden vegetables are very small, two or three caterpillars can in a single night work terrible havoc in young vegetables grown in rows. This was the case at Ottawa last spring where the larvæ of this species worked at the same time with the caterpillars of the White Cutworm (*Carneades scandens*, Riley, Fig. 13) and the Red-backed Cutworm (*Carneades ochrogaster*, Gn.) and all three species were particularly troublesome in radish beds.

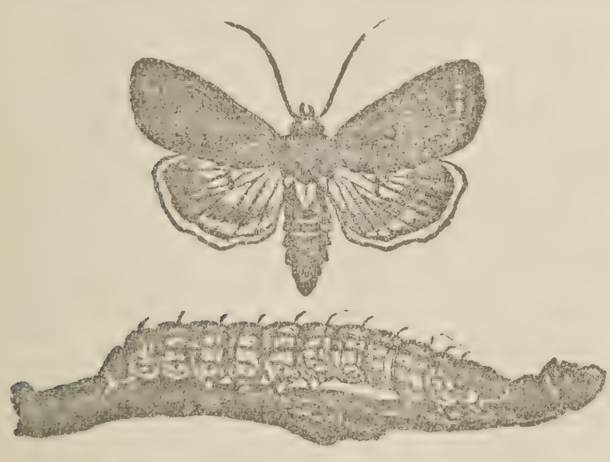

Fig. 13.—The White Cutworm.

THE WHITE-CUTWORM (*Carneades scandens*, Riley), "The Climbing Cutworm" of Dr. Riley, is an uncommon species at Ottawa and has not been sent in from elsewhere, although it is recorded as having done much damage to orchard trees in Western Ontario some years ago. The full-grown caterpillar measures about $1\frac{1}{2}$ inches in length. Its general colour is a pinkish white. The head, the thoracic feet and the thoracic and anal shields are yellowish-brown, dotted with minute black points The spiracles are deep black and the piliferous tubercles very dark, but not so black as the spiracles. This cutworm is easily recognized by its delicate whitish almost glaucous colouring. I was surprised to find it in large numbers at Ottawa in a garden with only two small poplar trees growing near. These were in no way injured, but it seemed as though the cutworms spread from a bed of Couch-grass (*Agropyrum repens*, Beauv.) which was growing at the base of one of these trees. The White Cutworm passes the winter about half grown, but in the piece of sandy land where the attack

referred to occurred some individuals did not revive until a surprisingly late date last spring, namely, the end of May. Some half grown specimens were dug from the bed of Couch-grass in November last. The moths expand about 1½ inches across the wings. The general colour of the forewings is pearly bluish-gray, tinged in some specimens with pink or brown scales; different specimens vary very much in distinctness of the transverse lines, but all show a well defined white subterminal line shadowed on the inner side by a row of dark triangular marks, and the reniform spot shows more distinctly than any of the other markings. Hind wings whitish, with a broad, pale fuscous band and discal spot. Head and body concolorous with the forewings.

Remedies.—When it is known that cutworms are abundant in gardens or even in fields, much can be done by the use of well-known and well tried remedies to destroy them and prevent injury. Several correspondents have borne testimony to the benefits of clean culture, by which all haulms, vines, stems and leaves of crops which had been gathered were promptly destroyed and the land kept free from weeds, so that the female cutworm moths when egg laying were not attracted to the spot. The banding of freshly set out annual plants, either with rings of paper or tin, has as usual given good results. An enterprising Ottawa firm, Messrs. Taylor and Gilbert, has put out a device made of a specially prepared stiff paper 10 inches long by 3 wide, called the Taylor Plant Protector for tobacco, cabbage, tomatoes, etc. These are stated to be a sure protection against cutworms, cold winds, light frosts, etc. The price, less than $1 a thousand, brings them within the reach of all. A great many were used at the Experimental Farm both in this Division and by the Horticulturist and were found to be extremely satisfactory. Cutworm injuries are of so much interest to every grower of vegetables, flowers and fruits in all parts of the Dominion, that I think it well to draw attention to the above device. I may mention that identically the same thing has been used for many years by Mr. George Thurber, of Upton Village, Que., to protect tobacco plants from frosts and cutworms.

The most striking results have been obtained from the use of the poisoned bran remedy, which consists of a mixture of bran and Paris green in the proportion of 50 of the former and 1 of the latter. In making this mixture (which may be applied either wet or dry) it is best to dampen the bran slightly with water containing a little sugar. After mixing thoroughly, so that the whole mass may be permeated very slighly with moisture, add the Paris green by shaking on a very little at a time and stirring it in. If the Paris green be added to the bran when it is perfectly dry, it will, owing to its weight, sink at once to the bottom when stirred. If it is desired to use this mixture as a wet application, more sugar and water must be added until it is of about the same consistency as porridge; but if to be used dry, a little more dry bran may be added until the mixture will run through the fingers easily. Mr. F. A. Sirrine, of Geneva, N.Y., drew attention to the fact that the mixture could be used dry with even better results than when applied wet. It is far easier to distribute and lasts longer without getting mouldy. A convenient implement for distributing this poisoned mixture, among crops which are grown in drills or rows, is a combined wheel hoe and seed drill. The seed box is filled with the poisoned bran, and lines of it are run across the field or along the rows close to the crop. In sandy land it was found convenient first to run a shallow furrow and then drop the bran into this shelter, which prevented the bran from being blown away by the wind. Strange as it may seem, it certainly appeared as if the bran mixture was more attractive to the cutworms than the living plants.

This remedy is, after all, only a modification of the poisoned trap remedy which has been used so successfully for many years, and which will continue to find favour with many, as green succulent vegetation suitable for the purpose is nearly always to be had, for it must be remembered that any weed will answer the purpose, whereas bran or shorts would have to be purchased.

THE CUTWORM LION *(Calosoma calidum*, Fab.*)*.—Cutworms have many enemies. In addition to various insectivorous birds and small mammals, there is a host of parasitic

Fig. 14.—Cutworm Lion beetle.

and predaceous insects which hunt them out and devour them. One of those most often inquired about is the Fiery Ground beetle (Fig. 14) and its voracious black grub, the Cutworm lion (Fig. 15). Specimens of these are sometimes sent in by observant correspondents. The beetle is a large showy and bold species, which is seen in pastures running about quickly and hunting for its prey. Too often, we fear, through ignorance as to its good offices it is destroyed by the many thoughtless people who seem to think that every insect seen should be stepped upon and killed. The appearance and habits of this good friend of the husbandman should be known to every one. The beetle is truthfully portrayed life size at fig. 14. It is a brownish-black beetle, having the wing cases spotted with coppery red in nearly all of the eastern specimens, although occasionally a green spotted specimen is seen. In British Columbian specimens the spots are almost invariably green, the red spotted form being exceedingly rare. Both as a perfect beetle and as a grub (Fig. 15) this insect destroys enormous numbers of cutworms. The following letter is similar to many others which have been received concerning this useful insect:

Fig. 15.—Cutworm Lion.

"Mattawa, June 25.—I applied to you last June for instructions how to fight the cutworm which had made a complete havoc of my garden, and I received your valuable treatise on insects that are destructive which gave me valuable instructions. I followed your advice and kept down weeds during the later summer and in the fall. After I got the crops off I cut all weeds in field corners, raked them up together with all potato tops and other refuse and burnt all; the result is that this year, while the cutworm has destroyed everything in my neighbours' gardens, they have troubled me very little; in fact, nothing to complain of, for of 2,000 plants transplanted, I have not had two per cent loss caused by the cutworms, and in plants grown from seed what little harm they may have done was not perceptible. I inclose you a specimen of a little insect that seems to be a mortal foe to the cutworms. One day recently I noticed a cutworm making very fast movements and contortions, so I picked it up and found one of these insects fastened to it just at the back of the head. I put both into a tin can and watched for the result of the combat. Several times I caused the insect to loosen its hold and placed each as far as possible apart; when the insect was let go it would immediately attack the cutworm again, always trying to fasten about the back of the neck. The result was that the cutworm was dead in twenty minutes. On Thursday last I found the inclosed specimen and then secured a cutworm and put both into a can, when the combat of the few days previous was renewed, with the same result. I put two more cutworms, one each time, into the can, and the black grub killed both."—[C. G. Hurdman.]

THE PEA MOTH (*Semasia nigricana*, Steph.).—In previous reports I have referred to the common injury to green peas, particularly the large late garden varieties, by the caterpillars of a small moth. During the past summer this insect was found in many districts, where it had doubtless always occurred, but from which no reports had been received. One of the localities where the insects has done most harm is Constance, in Huron Co., Ont. Mr. John McMillan, M. P., puts the loss in 1897 at no less than one-third of the crop. Up to the present no specimens of the moth have been caught in the field, but some specimens were reared in the insectary during 1897, which emerged between the 12th and 15th of July, and last summer three more specimens emerged at the same dates, namely, from 13th to 15th July. This would indicate that the natural time for egg laying is not till after the middle of July. Therefore, if peas are planted in good time and of early varieties—of which there are now several of high quality—good crops of green peas for the table can be secured before they are liable to be attacked by the caterpillar of the Pea Moth. At Ottawa several varieties of the small early peas can be picked by the first week in July, and the first crop of all the

best large varieties before the end of the month. The caterpillars of the Pea Moth would not be large enough to enter the pods and injure the green peas at earliest before the end of the month; consequently, at Ottawa and in localities with the same summer climate, green peas for the table can always be grown if early varieties are chosen and seed is got into the ground in good time. Mr. W. T. Macoun, Horticulturist of the Central Experimental Farm, has furnished me with the following list of what he considers the six best early varieties and of the dates when they were ready for picking:—

Alaska	June 17	Gradus	June 18
American Wonder	" 17	Nott's Excelsior	" 20
Gregory's Surprise	" 17	McLean's Little Gem	" 23

In his annual report for this year is given a list with dates of maturing of 25 of the best varieties of all kinds. Where peas are grown for the seed they will be injured in districts where the Pea Moth is prevalent. Experience would indicate that early sowing is in all cases advantageous, but it is also possible that late sowing, so as to hold back the podding, if possible, late enough to escape the season of egg-laying, might give a crop of uninjured seed.

THE PEA WEEVIL (*Bruchus pisorum*, L.).—This perennial pest is, year after year, the cause of enormous loss, notwithstanding the fact that millions of the beetles are destroyed every season in the "bug houses" of the large seed dealers. Prof. C. C. James says in his November *Crop Report*:—"Pease seem to have been the most unfortunate of the grain crops. The drought of the early part of the summer and a frost about the 10th July told upon the growth, and the bug made its appearance in nearly every section of the province. Some of those reporting are inclined to take a discouraging view of the outlook for pea growing, owing to this pest."

It is probable that there has been some confusion in the reports of which the above extract is a summary, between the injury of the Pea Weevil and that of the Pea Moth. The distribution of the Pea Weevil is very much more restricted than that of the Pea Moth, and there are large areas in the province of Ontario where the highest quality of seed pease can be grown without any danger of infestation by the Pea Weevil.

THE BEAN WEEVIL (*Bruchus obtectus*, Say).—*Attack.*—Small beetles closely resembling in shape and movements the Pea Weevil, but only half its size, namely, $\frac{1}{10}$ of an inch long, oval in form, with the head bent down and more or less concealed as seen from above, and prolonged into a short squarely cut snout. Antennæ distinctly jointed and enlarging towards the tip; the first 4 and the last joints reddish. The wing covers marked with ten impressed and dotted longitudinal lines. The whole body covered with short silky hairs. The lines on the wing covers are broken up into pale yellowish dashes and dark brown spots. The tip of the abdomen extends beyond the wing covers and is of the same reddish tinge as the tips of the antennæ and the legs, but is covered more or less with short silky hairs and bears a central white line, but there is no appearance of the two black spots which are so conspicuous in the Pea Weevil.

The life-history of the Bean Weevil differs in some important points from that of the Pea Weevil. The eggs of both are laid upon the pods while these are young and tender. On hatching, the young grub of the Bean Weevil eats its way inside and penetrates one of the forming beans, several grubs entering a single bean, each one forming for itself a distinct cell. They become full-grown and change to pupæ in the autumn and a little later to the perfect beetles. The date of emergence from the seed depends very much, as in the case of the Pea Weevil, on the temperature in the autumn months; it may be in the late autumn or not until the spring; when the seed beans are stored in a warm building, the beetles may emerge at any time through the winter. One of the important differences between the life-histories of the Pea and Bean weevils is that, whereas in the case of the former the young grubs can only enter the soft green seeds, those of the Bean Weevil can propagate for three or four generations in the dry stored seeds. This fact renders the well known domestic remedy for the Pea Weevil of holding over the seed for two years quite ineffective in the case of the Bean Weevil; that is, if a

bag of pease infested with Pea Weevil were put away for two years, the Pea Weevils would emerge the first spring and die in the bags. But, in the case of a bag of beans infested by the Bean Weevil kept in the same way, the beetles on emerging would at once set to work laying eggs upon the beans. The young grubs when hatched would penetrate the dry seeds and go through all their stages, and this breeding might be repeated as long as the supply of beans lasted. Curiously enough, the Pea Weevil does not bore holes through the paper or cotton bags in which infested seed has been stored, but in the case of the Bean Weevil such bags are readily perforated and the beetles escape,—frequently, when this happens in houses, as is sometimes the case, to the great consternation of the inhabitants.

The Bean Weevil seems to be a cosmopolitan species, the original home of which was in Asia. It was probably introduced into America through commerce and has been the cause of considerable damage in various States of the American Union. It has been mentioned in the reports of several United States entomologists, full articles being given by Professors Riley, Popenoe and Lintner. There has been a great deal of discussion as to the proper name of the species. The last decision seems to be that the beetle should be called *Bruchus obtectus* of Say. The Bean Weevil has never been recorded as an injurious insect in Canada until the present year, when I received from Mr. B. Gott, of Strathroy, Middlesex Co., Ont., specimens of the beetles and some seed beans which had been entirely destroyed for seed or food purposes. Each seed had been so perforated and the contents eaten away that it could be crushed with gentle pressure between the fingers. These specimens answered in every particular to Dr. Riley's description of *Bruchus fabæ* given in his *Third Missouri Report*, but authorities now consider that *B. fabæ*, Riley, and *B. obtectus*, Say, are identical.

Mr. Gott stated that the beans had been held over from the spring in strong paper bags and put away in a cool room. At the time of his writing, December, 1898, large numbers of the beetles had been found in his house. They were thought at first to be Pea Weevils, but Mr. Gott noticed that they were different, and after some search found that they came from the bags of beans, of which the paper was perforated with numerous holes.

Remedies.—As in the case of the Pea Weevil, the best remedy for this insect is the destruction of the weevils inside the beans as soon as possible after the crop is ripe. Fumigation with bisulphide of carbon is the best treatment in every way. It must not be forgotten that this liquid and its vapour are very dangerous to use, owing to their extreme inflammability. The most convenient way to fumigate seed is to place it in an ordinary coal oil barrel and pour on the beans one ounce of the bisulphide of carbon for every 100 pounds of grain, then close the barrel tightly, first with a wet canvas or cloth and, on the top of this, boards which should be left undisturbed for two days at least.

THE CARROT RUST-FLY (*Psila rosæ*, Fab.), mentioned in my last report, has been sent in as having appeared in injurious numbers at two new localities in the province of Quebec and also occurred in small numbers at Ottawa. This year white field carrots were attacked, as well as red ones. The semi-transparent yellowish maggot $\frac{1}{4}$ of an inch long perforates the roots in every direction, leaving dirty brown burrows. The maggots are blunt at the tail end, but taper towards the head, where is a black hooked tip forked at the base, by means of which the maggots burrow their way through the roots. The pupa-case is reddish-brown and, as a rule, is found in the earth outside the carrots. The mature fly is $\frac{1}{4}$ of an inch long, bright shining black with yellow legs and red eyes. There are at least two broods, if not more, in a season.

This is a serious pest of the carrot, rendering the roots quite unfit for table use. Its occurrence, however, has been intermittent, bad attacks one year being sometimes followed the next season by a total absence of injury.

"Knowlton, Brome Co., Que., July 6.—I send you to-day by mail a little box in which are a few carrots badly infested by a small white maggot. Nearly one-third of my patch of carrots are dead from the effects of it, and it is only a few days since they

began eating them. Can you give me any information as to what to do to get rid of them? What is it that lays the eggs? It is something new to me as I never noticed them before."—[J. Raymond Ball.]

"Quebec, Oct. 18.—I send you herewith a White Belgian carrot. My crop this year has been almost ruined by this disease, which you will be able to examine on the samples sent to you. Please tell me what is the matter and how to prevent it."

"Quebec, Oct. 27.—In reply to your inquiry as to whether my crop is the only one in this neighbourhood which has been injured by the Carrot Rust-fly, I beg to inform you that this year is the first that I have known the carrots to be injured by this fly. I secured a superb crop from the same field last year without any trace of the disease. My farm is situated at Ste. Marie, Beauce, and all the crops of carrots in the district have been attacked by the fly this season."—[A. B. Dupuis.]

Remedies.—Spraying the carrots along the rows with kerosene emulsion, 1 part to 10 of water, by means of a knapsack sprayer, or sprinkling along the rows dry sand, land plaster or ashes, with which coal oil has been mixed at the rate of half a pint to 3 gallons of the diluent, or crude carbolic acid at the rate of half a pint in 5 gallons, are the only applications which I know to have been used to any advantage. This should be done once a week through June from the time the roots begin to form and particularly after the rows have been thinned. Late sowing has also been found very useful.

Changing the location of the beds as far as possible from infested land has also been attended with excellent results and this common sense precaution should always be practised, when possible, in the case of all attacks of injurious insects. Where carrots are stored during the winter in sand or earth, this, of course, must be treated to destroy the pupæ which leave the roots and enter the soil to pass their last preparatory stage. Miss Ormerod suggests that this earth might be put into a wet manure pit so as to prevent the hatching out of the flies. Should neither of these methods be convenient, at any rate, the earth might be buried in a deep hole dug in the ground for the purpose.

THE TURNIP APHIS (*Aphis brassicæ*, L.)—One of the worst attacks upon root crops this year has been by the Turnip Aphis. In many parts of Ontario Swede turnips were badly injured. In Manitoba, likewise, an outbreak of this pest was brought to my notice by Mr. Bedford. The following extracts bring out the chief points upon which information was asked by correspondents:—

"Eddystone, Northumberland Co., Ont., Sept. 2.—On account of the very hot weather, lice are threatening to destroy the turnip crop in this part of the country. Is there any cure or preventive for it? Can spraying be successfully done?"—[W. G. Sargent.]

"Sherwood, York Co., Ont., Nov. 25.—In reply to your letter I would state that lice on turnips are not an entirely new pest, but they have never appeared in such numbers or with such destructiveness as this year. They have appeared in past years in small patches and were not considered very damaging. I think the reason that they were so numerous was the dry weather, as we had no rain from 1st July till the beginning of September, and it was exceedingly hot also. It wilted the mangel leaves in some localities. In the townships east and south of us, where they had more rain, the injury to the crop was not so great. In answer to your other question, I notice that the pest was destructive on all soils except perhaps some very low wet soils where sufficient moisture was obtained to keep up a steady growth."—[James H. Keffer.]

"Morden, Man., Sept. 28.—I send herewith a turnip leaf infested with some sort of insect. Last fall the same insect attacked the turnips, destroying the crop entirely. The root starts to decay as soon as the plant is attacked. All the turnips in this district went the same way. I should like to know what can be done to save the crop another year. I am taking up those turnips not already affected.

"Morden, Man., Dec. 28.—When you replied to my inquiry *re* turnip aphis, you asked me whether there had been much damage done in this neighbourhood. I have been inquiring of those who grow turnips, and find that nearly all the turnips in this district were damaged. In some cases the turnips were not attacked till late in the fall, and these were not damaged to any great extent."—[Alfred Bradshaw.]

The plant-louse which does most harm to the Swede turnips in Canada, is the same species which is also sometimes destructive to cabbage and is better known as the Cabbage Aphis. It does not usually appear on turnips until August, and is stated by many correspondents to be worst in dry years. There is a general impression that nothing can be done to prevent injury, and as a consequence these insects are, as a rule, left unmolested and a great loss sometimes occurs.

Remedies.—At the time these plant-lice first appear in fields, they are nearly always found in patches of restricted area. These should be looked for at the time the turnips are hoed and thinned, when good service may be done by simply hoeing out the infested plants and, having pulled some earth over them with the hoe, then pressing it down firmly with the foot. When the plant-lice are too numerous for this simple treatment, the plants should be promptly sprayed with a knapsack sprayer, using as an insecticide kerosene emulsion, 1 part to 9 of water, or whale-oil soap, 1 pound in 8 gallons of water.

ROOT MAGGOTS in turnips are seldom complained of in the West, where radishes are grown to the greatest perfection. Occasionally, however, there is a local outbreak of these troublesome insects. Mr. T. N. Willing, of Sylvan Glade, near Olds, Alta., sends specimens of the Cabbage Root-maggot (*Phorbia brassicæ*, Bouché), which, he says, "are from a larva about $\frac{3}{8}$ of an inch long, whitish with black hooks at end, which feeds in the Swede turnips. From one small turnip I found about 75 had entered the sand in which I had placed the turnip, and were in the pupa form. I inclose some with the flies. I had the turnip in the house about three weeks before these flies hatched out. Quite a large proportion of my turnips were damaged by this fly. I suppose it would be well to change the location of my turnip patch next season."

There were, as usual, inquiries from several other parts of Canada where the maggots of this fly are known to occur injuriously, one of the worst occurrences being along the shores of the lower St. Lawrence in the province of Quebec, where sad havoc was wrought in the gardens of the poor fishermen, who have to depend to a large measure on the products of their gardens. An account of this outbreak was sent to me by Dr. A. Mackenzie Forbes, of Montreal.

Remedies.—A sure remedy for these troublesome maggots is still much needed. Every year they are the cause of much loss in crops of great importance to a large number of people, such as cabbages of all kinds, turnips, radishes, onions, and sometimes beans and corn. A great many experiments have been tried with the object of discovering something of use. Many materials give partial immunity in ordinary seasons, but in bad years everything seems after a time to fail.

With onions and radishes, kerosene emulsion of the ordinary strength, 1 to 9, or carbolic soap-wash sprayed along the rows once a week gave tolerably good results, indeed some of the best results of many applications tried. The carbolic wash was made as follows: Dissolve 2 quarts soft soap in one gallon of boiling water, add 1 pint crude carbolic acid; when required for use, take 1 part with 50 of water. The most satisfactory application, but only to a small measure and early in the season, was White Hellebore or Pyrethrum powder dusted dry along rows of radishes at the time they appeared above ground and once a week afterwards. This is only applicable on a small scale. Experiments with kainit showed that this material assisted the plants very much in outgrowing injury, which in the case of cabbages is of very great importance. Kainit has also insecticidal value; but not, I think, to the degree which is claimed for it. It was tried (i.) broadcasted along the rows of onions and radishes, (ii.) sunk in a drill close to the rows and (iii.) in solution. When sunk in a drill it seemed to give better results than with the two other methods. In solution, when used strong enough to affect the maggots, it also injured the bulbs of the radishes, causing black spots, which afterwards rotted. Onions, however, were not injured, and the treated rows were decidedly better than the untreated. Experiments with cabbages showed that the best results were secured with a mixture of 4 ounces of kainit and 4 ounces of hellebore in $2\frac{1}{2}$ gallons of water, half a teacupful being poured round the base of each cabbage after pulling away the soil down to the true roots and applied in the third week of June, just as soon as the maggots were detected.

Through the kindness of Mr. M. V. Slingerland, of Cornell University, I was supplied with a number of the Goff tarred-paper cards. These are hexagonal pieces of ordinary tarred building paper, 3 inches in diameter, with a slit from one angle to the centre, where there is a star-shaped perforation to allow the placing of the card around the stem of a young cabbage. These were asked for rather too late in the season to give them a fair trial, but the plants upon which they were tried were well protected by them, and all those growers of cabbages who have used them speak highly in their favour.

POTATO INSECTS.

The potato crop in Ontario has been a good one. The seed was got in early and the plants suffered no checks from severe frosts. The Colorado Potato Beetle was less destructive than usual. Fine weather at the time of digging, except in some parts of the Maritime Provinces, allowed the crop to be got in in excellent order. There were very few complaints of insects or potato rot. In Manitoba and British Columbia the only adverse reports were from the drier sections, where in some instances the sets had failed to sprout. This was almost entirely where the tubers had been cut before planting. Moderate-sized whole potatoes had given by far the best results. In the Maritime Provinces potatoes were not so favourably reported upon as usual, owing to the wet autumn. Mr. B. W. Chipman, the Secretary for Agriculture of Nova Scotia, in his November *Crop Report*, says: "The potato crop this season, owing to the rains, which caused a great deal of rot, is only 68 per cent of an average, just the same as last year, but the prices have been fair." In Prince Edward Island where potatoes are a crop of very great importance, Father Burke estimates that there was only half a crop. He says: "The crop came up well and showed every sign of being large. The potato beetle came so late that many thought we were going to escape it. The wet early season was against its spread; later the beetles multiplied fast enough, but were controlled by Paris green, which everybody but those a thousand years behind the age now uses. The potato beetle did no injury to our crop this year." Several correspondents in Nova Scotia, Quebec and Ontario refer to the small losses from the Colorado Potato Beetle, but in Manitoba where this insect is very seldom a serious pest, it occured in injurious numbers in several places and required constant attention.

White Grubs and Wireworms have been reported as doing more harm to potatoes than for many years, and unfortunately nothing can be suggested as a remedy. In Nova Scotia where wireworms are sometimes very destructive in potato fields, it is a practice, when digging or ploughing up a crop in infested land, to pick up the potatoes immediately they are dug, when most of the wireworms will be taken with them from the field. After a short time, the wireworms will leave the potatoes and, if the crop is gathered in sacks or in carts, when the tubers are emptied out the wireworms will be found at the bottom and can be killed.

The Four-lined Leaf-bug (*Pœcilocapsus lineatus*, Fab.).—A somewhat unusual attack on potatoes, which early in the season appeared as if it might prove serious, was by the Four-lined Leaf-bug at Carrville, York County, Ont. Mr. J. Lahmer sent specimens and told of their ravages on some rows of potatoes which he had seen in a neighbour's garden. In acknowledging receipt the usual remedies for sucking insects were given and the life-history of this particular one was described. Later in the season, Mr. Lahmer wrote that the bugs did not spread further over the potato patch, but merely remained on the plants first attacked or on the bushes near by. The owner of the garden when he learnt that they were not a new pest lost interest in the matter and neglected to apply any remedy. The Four-lined Leaf-bug attacks many kinds of plants in gardens, having a special liking for sage and mint, currants, gooseberries and several other plants. The presence of the bugs is easily detected by the numerous brown spots about as big as a pin's head upon the leaves near the tips of the branches.

Fig. 16.—The Four-lined Leaf-bug.

The remedies consist of (I.) Spraying the nymphs or partially developed bugs which cannot fly, with a strong kerosene emulsion (1 to 6); (II.) The jarring or beating of the nymphs and perfect insects from the attacked plants into open tins containing coal oil and water; and (III.) The destruction of the eggs, which are always laid in the twigs of bushes, particularly the currant, near the tips; these are white, and, as they protrude slightly through the bark, when once seen they are easily recognized again, and thus this attack may be controlled to a large measure by winter pruning.

FRUITS.

The fruit crop of Canada has again been a good one. In Ontario, apples, as stated in the November *Crop Report*, were considered more than sufficient for home consumption; very large shipments were made to England and the United States from the western fruit-growing sections; pears, peaches, plums and smaller fruits were also shipped from many localities. From Nova Scotia, the other large fruit exporting province, Mr. R. W. Starr, of Wolfville, N. S., a successful fruit grower and shipper of many years' experience in the Annapolis Valley, writes: "The spring opened early; fruit trees showed a mass of bloom everywhere, but cold rainy weather set in, bees and other insects could not work and pollination was imperfect, especially among apples. Many orchards that showed much young fruit apparently well set, some ten days later, had the ground covered with young apples, leaving apparently very few on the trees. As the season passed on we had frequent showers, but the total rainfall was not more than usual. All the fruit that set healthily developed rapidly, and the extra size made up largely for lack of numbers; the export will, after all, be a good average quantity, say, 250,000 barrels, and the quality better than usual."

Mr. S. C. Parker, Secretary of the Nova Scotia Fruit Growers' Association, says: "The damage to crops this season by insects has, perhaps, been the least of any season in my experience. All insects noted in the orchard and garden were fewer in numbers than for some years past. The means of combating these different pests and the best remedies have been made so widely known that farmers are on the alert to clear them out when they show themselves. Cutworms were conspicuous by their absence. Curculio did not appear to be as destructive as usual, at any rate, did not materially lessen the enormous plum crop. There were no complaints of Codling Moth or Shot-hole Borer, and the Bud-Moth was not as common as usual. Apples were good, more than usually free from Black Spot; the prices were away up and there was a fair crop. There were two bad enemies, however, of plum trees: the Shot-hole Fungus (*Septoria cerasina*, Peck) has devastated many plum orchards, and I expect to see a lot of dead trees next spring; the Black Knot (*Plowrightia morbosa*, Sacc.) has been very bad. Many have about given over fighting it. With plums a drug on the market, the game is not worth the candle."

With reference to the prevalence of fungous diseases, Mr. R. W. Starr also writes: "In most plum orchards rot set in badly, and as a rule, there was more fruit left in the orchards than was picked for the market. Some kinds were worse than others, especially Lombards; whole orchards also were ruined by Leaf Blight and were bare of foliage when the fruit was two-thirds grown. The Japanese varieties seemed to stand a wet season better than the descendants of *Prunus domestica*, L. Burbank did especially well. Abundance seemed to be rather susceptible to Shot-hole Fungus. Most of our early peaches rotted on the trees. Red Rust Fungus on the quince formed lumps somewhat resembling Black Knot in shape. Currants and gooseberries were stripped of their leaves by a blight, and pears showed more Fire Blight than for many years. You will gather from the above that fungous diseases have been very prevalent. I think we must ascribe this to the dull showery weather. I have wondered how the apples escaped as well as they did. Former experience would have led me to forecast a very different result."

It is satisfactory to hear from Prof. F. C. Sears, the Director of the Nova Scotia School of Horticulture, at Wolfville, N.S., that "Spraying was much more generally practised this year than ever before, and the results were very satisfactory, especially so in the use of Bordeaux mixture to control the Black Spot of the apple and the Shot-hole Fungus of the plum. I held about fifteen spraying meetings in different parts of the province and induced fruit growers to experiment also for themselves. I sprayed some rows and left others. The results have been very conclusive in most cases."

In Prince Edward Island, Father Burke says: "Despite our spraying, we had our share of apple-worm, some sorts of apples being badly injured; the season being so wet, the Bordeaux mixture did not stay on long enough to do its work. Owing to the wet season, there was also a lot of Black Spot, but, on the whole, we have a fair apple crop."

In British Columbia, fruits of all kinds were abundant, but there was much loss from insect pests. The two worst enemies of the apple growers were the Apple-fruit Miner *(Argyresthia conjugella, Z.)*, and the small moth described by Walsh in *First Illinois Report* under the, as it has since been ascertained, rather inapt name of the Plum Moth *(Grapholitha prunivora*, Walsh*)*.

The fruit interests of the Pacific province are well looked after by the energetic officers of the provincial Department of Agriculture. The Deputy Minister, Mr. J. R. Anderson, and his Assistant, Mr. E. A. Carew-Gibson, have done excellent scientific work in investigating the botany and entomology of the province, particularly in solving some doubtful points in the life-histories of important enemies of crops. Mr. R M. Palmer, the Inspector of Fruit Pests, has devoted special attention to the practical questions of orchard treatment, of making known the best remedies for pests and the way to apply them, of keeping the provincial markets clear of infested fruit, and thus incidentally creating a better market for home products. British Columbia is blessed to a remarkable degree with a climate and soil suitable for the production of fruits of many kinds, and the wise and energetic measures which have been adopted and fearlessly carried out by the officials of the provincial government have certainly been attended with much success. Up to the present time, notwithstanding statements to the contrary, the Codling Moth has not been detected in any British Columbian orchard.

THE APPLE FRUIT-MINER *(Argyresthia conjugella, Z.)*, which has called for so much attention of late years by its injuries to apples in British Columbia, was again this year the cause of considerable loss. In mixed orchards containing several varieties of apple trees, I noticed last summer that crab-apples were more particularly attacked than the larger kinds. Mr. Palmer makes the following report on the occurrence of this insect in British Columbia during 1898:—

"Victoria, B.C., Dec. 15.—On the Islands, especially in the neighbourhood of Victoria, the Apple Fruit-miner *(Argyresthia conjugella)* has been very prevalent this year. The native crab-apple crop was a failure, and this pest attacked cultivated fruits (apples) to an alarming extent. It preferred cultivated varieties of crab-apples to ordinary varieties of apples, and a much larger percentage of larvæ completed their growth in infested crab-apples than in the finer fruit. The entire crop of many crab-apple trees (cultivated varieties) was completely ruined, being tunnelled in every direction, all through the pulp of the fruit. Every effort has been made to get infested fruit destroyed, as, although in 1896 some loss was sustained from the pest, it was not nearly so large as in this season, and I now apprehend there is some danger of the insect becoming a constant feeder on cultivated varieties at least of crab-apples, and possibly of some others.—[R. M. Palmer.]

An interesting account of a Japanese insect, *Laverna herelella*, Dup., which, if different, resembles in most respects the Apple Fruit-miner in a very remarkable manner, is given with an excellent figure in *Bulletin 10*, *New Series*, Div. of Ent., U.S. Dept. Agr., by Prof. Matsumura, of Sapporo, Japan. In a foot-note to this article, Dr. Howard has suggested, from the resemblance of Prof. Matsumura's figure to bred specimens of the Apple Fruit-miner from British Columbia, which he was good enough to examine, the identity of the two insects. Although it is true the figure cited and the perfect moths

of the Apple Fruit-miner do agree closely, the habits of the larvæ as given by Prof. Matsumura (*loc. cit*) and as described in my annual report for 1896, differ upon what seem to be such important characters that for the present I can hardly think that the two attacks are by the same species. The writer of the article referred to says that the larvæ live only in apple cores, injuring the seeds, that there is usually only one egg deposited on each apple, and that the cocoons are made in the earth whenever possible.

The British Columbian insect very rarely attacks the cores and seeds of the fruit. There are usually several, two, three or more, larvæ in each apple, and the cocoons are made beneath flakes of the bark on the trees or beneath leaves or rubbish on the surface of the ground.

I have lately received the following interesting note from Prof. Enzio Reuter, of Helsingfors, Finland, on the occurrence of *A. conjugella* in Europe :—"I have read your report with great interest. *Argyresthia conjugella* has during the past summer infested the fruit of apple trees throughout the whole of Finland. This is owing to a total failure of sorb-apples (*Sorbus Aucuparia*, L.)* and bird-cherries (*Prunus Padus*, DC.), in which the larvæ commonly feed."

All efforts to discover the egg or the egg-laying habits of the moth have so far failed, and no proved, practical remedy is yet available. At Mr. Palmer's suggestion, many of the fruit growers in the districts where this insect has been troublesome, have adopted the wise precaution of picking and destroying every apple which showed the attacks of the larvæ.

Prof. Matsumura suggests the catching of the moths of the Japanese insect by suspending large-mouthed bottles containing sweet solutions beneath the trees at night; he points out that these should be closed during the day time so that many useful or harmless insects may not be destroyed.

THE PLUM MOTH or LESSER APPLE-WORM (*Grapholitha* [*Semasia*] *prunivora*, Walsh).—For many years British Columbian apple growers have referred to a small caterpillar which in every thing but size answered to the caterpillar of the Codling Moth. The insect was not abundant and all efforts to obtain specimens to rear the moth failed. Last year a few were secured by Mr. E. A. Carew-Gibson and successfully reared to maturity. The perfect insect, a small moth, was kindly identified by Dr. L. O. Howard, the United States Entomologist, and proved to be the same insect as was treated of and figured by Benjamin Walsh in his *First Report* as State Entomologist of Illinois, under the name of the Plum Moth (*Semasia prunivora*). Walsh bred specimens of the moth from plums, from the fungous growth known as the Black Knot of the plum, from the Cock's-comb-like hollow gall (*ulmicola*, Fitch) on the leaves of elms, which is produced and inhabited by plant-lice, and lastly from a hollow gall on the leaf of red oak. In addition to the above, the late Dr. C. V. Riley (*Am. Ent.* (*III*), n. s., I, 131) adds that he has bred the moth from galls on oak, from haws, from crab-apples and abundantly from cultivated apples. I have at different times bred the moth from apples and haws at Ottawa, from near Toronto and from Lachine, Que. I can find no reference in recent publications to serious injury to either apples or plums by this moth. Single specimens of the caterpillar have been sent in occasionally from Quebec and Ontario, but, as far as I am aware, they have never been sufficiently abundant to be more than noticed by the curious. Last year, however, Mr. R. M. Palmer expressed fears, from the numbers he was finding in British Columbian apples, that the insect might develop into a pest of importance. At that time he complained only of the commonest form of attack by the caterpillar, which is to feed beneath a web upon the skin of the apple, around and inside the cup at the calyx end, or occasionally to burrow more or less extensively under the skin. When visiting British Columbia last summer, in the last week of July, I was shown by Mr. Carew-Gibson a large number of apples which had been handed over to him by Mr. Palmer, which were very seriously infested, both by this insect and also by the Apple Fruit-miner. Upon cutting open several of the infested apples, I was surprised to find how exactly in many instances the work of

* In this country called "Mountain Ash" or "Rowan tree."

the larvæ of *G. prunivora* resembled that of the Codling Moth (*Carpocapsa pomonella*, L.). Not only was the skin and flesh just around the calyx eaten, but the apple was bored into extensively, the core being frequently reached and the pips eaten in precisely the same way as is done by the Codling Moth caterpillar. Every specimen was examined carefully and proved to be *G. prunivora*. This same fruit was also found, as stated above, to be badly infested by the Apple Fruit-miner, as well as the Lesser Apple-worm, both kinds occurring in the same apple.

"Victoria, May 8.—The specimen that I am sending is the only adult that I have managed to rear; you will note in size it is not more than half the size of the Codling Moth; it has also different markings and its larva never reaches more than half the size of the Codling Moth larva when full-grown. This is the insect whose larva is so often mistaken in this province for the larva of Codling Moth and reported as such. It is fairly common in some spots, but owing to its size cannot do so much damage to the fruit it attacks."—[E. A. Carew-Gibson.]

"Victoria, Dec. 15.—The larva of *Grapholitha prunivora* has been found this season widely distributed all through the lower mainland and the Islands as well. Although usually attacking apples, feeding at the calyx end of the fruit for about ½ an inch down, it is also often found inside the fruit, and has been been frequently mistaken for the larva of the Codling Moth (*Carpocapsa pomonella*). It has also occurred quite often in plums and prunes, and specimens of fruit so infested have been sent in or collected from the whole of the districts named.

"This pest and the Apple Fruit-miner evidently need more attention at the hands of our fruit growers in the future than has heretofore been accorded them. In the case of the Lesser Apple-worm, I think that spraying with Paris green as for the Codling Moth may be of considerable value. I shall be glad of any suggestion you can make as to dealing with these pests.

"A large number of the larvæ collected this season have been carefully attended to by Mr. E. A. C. Gibson, and it is hoped that a number of specimens of the perfect insects and perhaps some parasites will hatch out in the spring. Many specimens of fruit collected contained larvæ of both species."—[R. M. Palmer.]

From the past history of this insect, particularly in British Columbia, and after talking the matter over with Mr. Palmer and Mr. J. R. Anderson, who three years ago found numbers of apples badly infested in Capt. Gaudin's garden, at Victoria—from which, however, the insect has since entirely disappeared—I think it hardly likely that this caterpillar will develop into a serious pest of apples or plums. It is probable that the injuries of this year, which are certainly exceptional, were due to the failure of the wild crabs to produce fruit this year in British Columbia, and that both this insect and the Apple Fruit-miner were driven to cultivated fruits, as it is related in Dr. Reuter's interesting letter was the case with *Argyresthia conjugella* in Finland this year.

Should injury by the Lesser Apple-worm continue, I have no doubt, as suggested by Mr. Palmer, that spraying with Paris green should be the first remedial experiment tried.

Notes on the Lesser Apple-worm, by Mr. E. A. Carew-Gibson.

Aug. 16, 1897.—Received from Hornby Island, a number of apples infested with a small boring worm.

Sept. 17.—Found six larvæ from above apples spun up, five in the paper beneath the apples, using the paper fibre for their cocoon, and one spun up on the cork of a small specimen bottle using cork dust for its cocoon; all the spun up larvæ at this date unchanged. The specimens are $\frac{3}{8}$ inch long, $\frac{1}{16}$ inch in diameter, tapering slightly towards both extremities; reddish pink to pale pink in colour, lightest in colour between the segments. Head smaller than 1st segment, with blotchy darkish brown markings, thoracic and anal plates also darkish, marked with brown. Body covered with white bristles, with finely dotted surface to the skin (under the microscope). Surface with lumps and depressions. Very active when placed in the sunshine, evidently at once seeking shelter for spinning up. The larva spun up on the cork very closely covered over with cork dust.

May 7, 1898.—One very active little moth emerged.

E. A. Carew-Gibson.

The moth expands about $\frac{5}{8}$ of an inch across the wings. The ground colour of the front wings is black, with large patches of rusty red and a central steel blue blotch. Along the costa are seven very conspicuous short white streaks, arranged 2, 2 and 3 together, of which the longest are the 1st, 3rd, 5th and 7th; these streaks are nearly parallel to each other and are obliquely directed toward the posterior angle of the wing. The hind wings are dusky gray at the base, shading into black at the tip.

The other insects which have attacked fruit trees during the past summer are well known species. Of these none have called for more attention by their excessive numbers than the TENT CATERPILLARS, which swarmed on forest and orchard trees in many sections of almost every province of the Dominion.

Enormous numbers of Tent Caterpillars of the two common species, the Forest Tent Caterpillar (*Clisiocampa disstria*, Hbn.), and the American Tent Caterpillar (*C. Americana*, Harr.), occurred in the woods and on trees in gardens and orchards for many miles around Ottawa and through the counties of Carleton, Russell and Grenville; nor were they confined to this part of the province, for specimens or letters of inquiry came in from every direction. Aspen poplars, maples and basswood seemed to be the favourite food plants, but where the caterpillars were abundant the foliage of all plants was eaten.

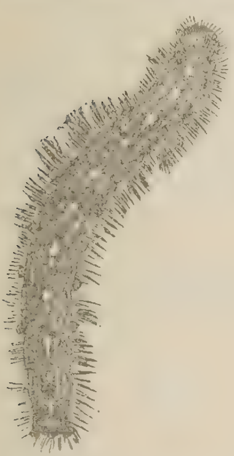

Fig. 17.—American Tent Caterpillar.

"Victoria, B.C., Dec. 15.—On the Lower Mainland the most troublesome pests of the season were the Forest-tree Tent Caterpillars. They were present in countless thousands and fruit trees in proximity to native trees such as alders and willows, where the pests hatched undisturbed, were in danger of being defoliated, even when considerable attention was devoted to fighting the pests. Fruit trees from which the leaves were eaten, put on foliage again later in the summer, but went into winter in poor condition to withstand vicissitudes of weather. Fortunately, by far the larger proportion of the larvæ were parasitized and egg masses of the pests are not nearly so numerous as last year; besides this, fruit growers were roused as a rule to the danger from these voracious insects and better prepared to fight them both by the destruction of eggs during the winter months and by means of Paris green spraying later on."—[R. M. Palmer.]

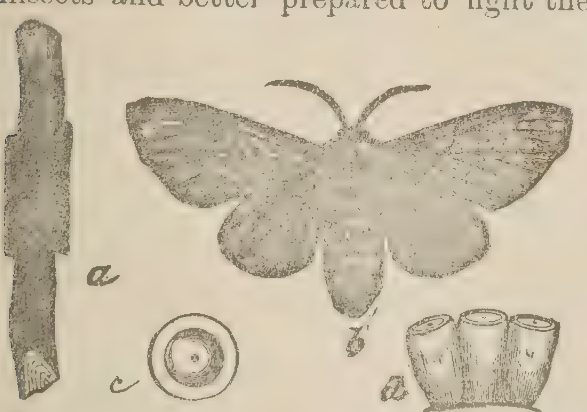

Fig. 18.—The Forest Tent Caterpillar: *a*, egg cluster on twig; *b*, moth—natural size; *c*, *d*, eggs—enlarged.

When I was in British Columbia last August, Mr. T. A. Sharpe, of Agassiz, drew my attention to the fact that a very large percentage of these caterpillars had been destroyed by a very fatal disease after they had spun their cocoons. He examined one hundred cocoons before he found one containing a living pupa. Unfortunately no such state of affairs happened in the Ottawa outbreak, for at the present time the egg clusters (Figs. 18*a* and 19) are to be found abundantly on trees and shrubs in every direction. On one small cherry tree 10 feet high, I collected no less than 37 egg clusters. The eggs in every one of them appeared to be in a healthy condition, and the young caterpillars hatched out in thousands in my office. There is the greatest necessity for all who wish to save their trees to take steps next season, in the first place, to clear from the trees during the winter such eggs as can be reached, and to provide themselves with spraying apparatus so as to be ready to destroy the caterpillars

Fig. 19.—Egg cluster of the American Tent Caterpillar.

next spring while they are still small, using the ordinary standard mixture for foliage-eating insects, namely, 1 pound of Paris green, 1 pound of quick lime, and 200 gallons of water.

THE PLUM CURCULIO (*Conotrachelus nenuphar*, Hbst.).—Plum growers have pretty generally adopted spraying with Bordeaux mixture and Paris green as the best remedy against the Plum Curculio upon plums. The treatment, however, is by no means claimed to be a perfect remedy, although I believe that the saving in the quality of the crop will always make it pay handsomely to spray plum trees, and in the mean time it is the *best* remedy. The fact that most of the large plum growers have adopted spraying as a regular practice speaks for itself and shows that it pays them to do so. Spraying cherries and peaches has not been quite so satisfactory as in the case of the plum, and upon the apple to which the Plum Curculio is sometimes very destructive it would appear that spraying is even less effective. Nevertheless, it pays to spray as in the other cases.

In October last, I received through Mr. W. T. Macoun, some specimens of apples which had been utterly ruined for the market by the Plum Curculio, being gnarled and indented wherever the beetles had bitten ("stung") them. At the same time the growers of the apples, Messrs. R. Jack & Sons, of Chateauguay Basin, Que., sent a bottle filled with specimens of Plum Curculio taken on the apple trees from which the injured fruit was sent. Messrs. Jack & Sons write :—

"Chateauguay Basin, Que., Nov. 8.—You ask if plums are badly affected by Curculio with us. They are, very badly, both on the farm and all round this section of country. I have known the pest sometimes to destroy the whole of the crop on some of the trees. You ask also whether the female uses the young apples to deposit her eggs in. That is the way in which most damage is done. Sometimes we have not been able to find a sound apple on some trees with about a bushel of apples on. Most of the apples had eggs deposited in them or had been punctured, and some of the apples would have as many as three or four eggs in them. We have noticed some apples injured within two or three days after the blossoms have fallen. We notice very little difference between sprayed and unsprayed trees. They seem to be very little affected by Paris green. Last season we used Paris green in the first two applications of Bordeaux mixture, *i.e.*, once before blossoming, and immediately after the blossoms had fallen, at the rate of 8 ounces to 50 gallons of water, and still they injured great quantities of apples. The kinds which they seem to have a preference for are Duchess, Yellow Transparent, Astrachan, Grimes Golden, and Golden Ball, but if these kinds are scarce they work on the other varieties. In fact, the Curculio does us more damage than all the other pests and fungous diseases combined. A good many apples fall prematurely with the larva in them. Do you think it would be any advantage to pasture the orchard with sheep, so that they would eat the fallen apples and so destroy the grub? We send you under separate cover samples of apples which have been injured by them."

"November 18.—Your favour of the 12th instant to hand. In it you ask how long it is since we noticed the Curculio destroying the apples. We would say that it is about six or eight years since we have noticed them doing any injury to any extent to apples, but they have troubled the plums for a good deal longer period. They also do considerable damage to cherries. We have along one of the line fences between our neighbour and ourselves, a row of common red plums which have been infested with Curculio as long as we can remember, but the place where the Curculio is worst is at the other side of the orchard. We intend to have these old plum trees cut down this fall and have the land cultivated for a couple of years. There is in a field next to the orchard a clump of hawthorns of which the haws have been infested with little grubs, but we have never experimented to see if they were Curculio or not. Perhaps you could give some information ? I notice that the Curculio does not seem to do so much damage where the trees are cultivated often."—[R. Jack & Sons.]

The above letters were in reply to questions which are well indicated by the answers given. Some of the apples forwarded by Messrs. Jack had from 5 to 25 punctures and were utterly useless for the market. It is well known that the Plum Curculio lays

its eggs in apples and that the larvæ can develop in this fruit, but most of the injuries in this case were of the nature of a hollow cavity beneath the skin, the flesh appearing to have been eaten out through a central orifice. Frequently these cavities were at the bottom of deep depressions, and there were no galleries in the flesh of the apple. That the injury to apples extended further than the immediate vicinity of Chateauguay Basin was shown by my receiving specimens injured in exactly the same way from Professor L. R. Jones, of Burlington, Vt., with the information that the injury was quite common on Baldwins and Greenings and that considerable injury had been caused in the State of Vermont. The advantage of attending to windfalls, either by collecting them or pasturing sheep or pigs in the orchard was pointed out, and the opinion was expressed that the grubs which had been found in the haws were more likely to be those of the true Apple Curculio (*Anthonomus quadrigibbus*, Say.) than of the Plum Curculio. The fruit of the hawthorn is nearly always infested by *Anthonomus quadrigibbus*, and, as far as my own experience goes, it is a very rare enemy of the apple. As a remedy for this attack on apples by the Plum Curculio, nothing further can be suggested than spraying the trees regularly with Paris green, beginning early and continuing as late as possible through the season. Where it is practicable, jarring the trees over large sheets placed on the ground and then destroying the beetles will, of course, reduce very much the amount of injury.

THE GREEN FRUIT-WORMS (*Xylina*).—The larvæ of two or three species of this genus were unusually abundant and destructive in some parts of Ontario last summer. Mr. W. M. Orr found them in many orchards when superintending the Provincial Government spraying experiments. He estimates the loss from these caterpillars at between 20 and 30 per cent. Mr. N. H. Cowdry, of Waterford, Norfolk County, Ont., sent specimens of the caterpillars, together with their work on young apples and pears. He said: "They seem to feed exclusively on the young fruit to which they are exceedingly destructive, but they do not touch the foliage. They are very numerous about here, and, owing to their habit of eating the fruit only, are hard to destroy by spraying." An account of injury by Green Fruit-worms, was also received from Mr. John A. Link, of Sombra, Lambton Co., Ont.

Fig. 20.—A Green Fruit-worm: *a*, caterpillar; *b*, moth.

At Aylmer, Wright Co., Quebec, large silver maple trees (*Acer dasycarpum*) and to a smaller degree other trees and shrubs growing near were almost defoliated by the larvæ of a species of *Xylina*, which were in such numbers that every tree trunk and fence was swarming with them in the third week in June, as they moved from tree to tree in search of food. Almost all the specimens collected died from injuries inflicted upon each other in the breeding jars. A single specimen of the moth was reared which seems to be *Xylina Grotei*, Riley. The caudal end of the pupa resembles that of *X. laticinerea*, Grote, as figured by Mr. Slingerland on Plate II. of his Cornell University *Bulletin 123*, except that the cremastral spines are less pronounced.

Another outbreak, not quite so severe as the one above mentioned, occurred at Niagara on the Lake, where large maples planted as shade trees were covered with these caterpillars to the great inconvenience of passers by in the streets. In this case, I think it hardly possible that many of these larvæ could have reached the perfect stage, for the trees were visited incessantly by warblers and other insectivorous birds who vied with a swarm of English sparrows in the branches above and numerous chickens on the ground below, in destroying every caterpillar that moved. It is several years since these insects have been abundant enough to call for special treatment, but similar outbreaks to those mentioned upon forest and shade trees occurred in the vicinity

of Ottawa in 1885. The caterpillars of three distinct species of moths are known by the name of the Green Fruit-worms. These resemble each other very much in appearance and habits. They are discussed in detail by Mr. M. V. Slingerland, in his characteristically careful and accurate manner, with beautiful figures, in Cornell University *Bulletin 123*. The caterpillars may be described generally as cylindrical in shape with heads almost as wide as the body. Colour, pale leaf-green, striped longitudinally and dotted with creamy white. The full-grown caterpillar measures from $1\frac{1}{4}$ inches to $1\frac{1}{2}$ inches in length by $\frac{1}{4}$ of an inch in diameter. The food consists of the leaves of the apple, pear and several kinds of forest trees; the maple, poplar, hickory, wild cherry, box elder and the buds of roses are recorded among their food plants. Their greatest injuries, however, are to the fruit of apples and pears.

The moths vary considerably in appearance, but are characterized by the cold ash-gray colour of the front wings, which are variegated with darker gray. The most constant characters seem to be: a pale space at the base of the front wings and on the upper half, the pale upper part of the orbicular spot and the dark sub-terminal line. The expanse of the wings is from $1\frac{1}{2}$ inches to $1\frac{3}{4}$ inches.

"The moths are night fliers, remaining concealed on the bark of the trees or in secluded places during the day. Most of them appear during September and October, and, hibernating in sheltered places, appear again in March, April and May; some evidently remain in the ground as pupæ over winter, the moths not appearing until spring. They are readily attracted to lights or sweetened baits at night, and are 'often found in maple groves while sugaring is going on. Sometimes sap-pails are found in the morning with the surface of the liquid completely covered with the moths.'" (M. V. Slingerland, *Bulletin 123.*)

THE SAN JOSÉ SCALE (*Aspidiotus perniciosus*, Comstk.).—Since the passing of the San José Scale Act, on the 13th of March, 1898, every effort has been made, both by the Federal Government and the Provincial Government of Ontario, to detect any occurrence of this extremely injurious insect and to eradicate it with as little delay as possible. A thorough examination has been made of that section of the province of Ontario in which it was known that colonies of this scale insect had been found in 1897. Wherever infested trees were detected, they were dug up and destroyed. Trees known to have been imported from States or nurseries in which the scale had occurred during the last few years were followed up and examined in the orchards where they had been planted. It is satisfactory to know at the conclusion of this inspection that the prevalence of this insect in Canadian orchards is far less than it was feared last spring might be the case. The only locality where a new occurrence of special interest, from its northern latitude, has to be recorded is at Guelph, Ont., where the winters are sometimes very severe, the thermometer occasionally falling as low as 15 degrees below zero, Fahr. The scales in this case were imported on pear and plum trees and had passed through at least two Canadian winters; although the scales had survived, they had not spread to other trees. The passing of the San José Scale Act has naturally given rise to a great deal of correspondence as to what kinds of plants come within the provisions of this Act and are prohibited from being imported into Canada from any country where the San José Scale is known to exist. In framing this Act, great care was taken by the Hon. Minister of Agriculture to interfere as little as possible with established lines of trade and only to prohibit such plants as it was thought were a source of danger to this country. It is known that the San José Scale is liable to occur in a living state, and that thus it might possibly be introduced, upon any woody-stemmed tree or shrub, except conifers, the stems of which do not naturally die down to the ground every year. Such plants, therefore, may not be imported into Canada from any country where the San José Scale has been found. A very few exceptions have been made to this rule in the case of some plants which are only grown in greenhouses. These exceptions were authorized by Order in Council at the time of the passing of the Act and made public through the *Canada Gazette*. They have also been published in the reports of the Entomological Society of Ontario, of the Fruit Growers' Association of Ontario, and of other societies. No further exceptions to the Act have been made, and in the case of such plants as

raspberries and some other small woody-stemmed shrubs it was considered wise by the Hon. Minister, for the present at any rate, not to allow these to be imported, even when cut right down to the roots, for fear that this cutting might not be done thoroughly enough. True herbaceous perennials, like the perennial phlox, dahlias, herbaceous pæonies, and perennial asters, the stems of which die back right down to the roots every autumn, can be safely imported and consequently are not prohibited. The scale has been known to spread occasionally on to several plants with herbaceous stems, but as it can never move again after once settling down on any plant, which it does within two days after birth, and as during its active life it must constantly be supplied with liquid food, even, were it introduced in the dormant condition in which it passes the winter on the stems of herbaceous perennials which had died down naturally, such scales could never revive nor propagate ; in the first place, they would have no food in the dead, sapless stems, nor could they move to search for it elsewhere, owing to the scales which they have formed over their bodies since they settled down, and also to the important fact that very soon after settling they undergo their first moult, from which time they are absolutely without legs or other means of locomotion. In the second place, they could not propagate because they pass the winter in a half grown condition, and being deprived of food it is impossible for them to reach maturity.

The question is frequently asked at farmers' meetings when specimens of the San José Scale are shown on pieces of twigs and branches, whether there is not danger of introducing the scale into new localities by this means. For the reasons given above, there is manifestly no danger to be feared in this direction. The only way in which the scale can be spread is by the migration of the young insects during the short time that they are able to crawl about. The sap in any piece of infested wood which could be conveniently taken to a meeting for exhibition dries up in a few hours and very few of the young scale-insects could be born before the females died, even if the wood were taken at the time when the females were bearing young, and then these young insects would have to find their way on to living trees before many hours or they would die. It has been objected that upon wood bearing the Oyster-shell Bark-louse myriads of the young have been found moving several weeks after the scale-bearing branch had been severed from the tree. It must be remembered, however, that the habits of the Oyster-shell Bark-louse and those of the San José Scale are entirely different. When mature, the female of the former, before dying, lays beneath her scale a large number of eggs, which remain unhatched for many months from autumn until the following summer, during which time, of course, being eggs, they require no food ; so it does not matter how dry the branch bearing them beneath their mothers' scales may be ; but whenever these eggs are brought under favourable conditions they will hatch and the young bark-lice appear. With the San José Scale, on the contrary, eggs are never laid, but the females bring forth their young alive and at that time must be constantly supplied with liquid food. As stated above, if the scale-bearing wood is removed from the trees during the period of dormancy in which the San José Scale passes the winter, all the scale-insects upon such wood are immature and must soon die. This period of dormancy lasts in Canada, at any rate, from the beginning of November till the beginning of June. Close study of this insect has shown that none but the immature insects live through the winter, and, further, that these do not begin to produce young until after a considerable time of active life and growth the following season.

The keen interest which has been aroused with regard to all insect pests by the advent of the San José Scale has also drawn attention to various other kinds of scale-insects which have been found upon Canadian fruit trees. Many kinds of these have been sent in for examination. The Forbes Scale, the Putnam Scale, the New York Plum Scale and the Scurfy Bark-louse were all found in some numbers upon orchard trees. Although widely spread through the province of Ontario, not one of them was sufficiently abundant in any locality to be considered a serious menace to fruit growers.

In addition to the above, the Oyster-shell Bark-louse is extremely abundant all through Canada and is very destructive.

The standard remedies for scale-insects are kerosene emulsion or whale-oil soap solution (1 lb. in 2 to 4 gallons of water), applied early in the spring, just before the buds open.

APHIDES OR PLANT-LICE have again this year been conspicuous in orchards. In the Niagara district the CHERRY APHIS (*Myzus cerasi*, Fab.), appeared in enormus numbers early in the season and, although it disappeared as mysteriously as it had come, in some places, in orchards of cherries, particularly the sweet varieties, it did a great deal of harm. Mr. C. F. Purdy, of St. Catharines, this year lost heavily from this insect, which in his orchard was far worse than last year. Mr. Martin Burrell, of the same place, writes: "I find in my notes that the Black Cherry Aphis was very abundant on 27th May. Under date of 2nd June, I find: 'Black Aphis breeding rapidly, very few *Syrphus* larvæ or lady-birds'. I have no other notes, but, on the whole, the later injuries were not as bad as in 1897. We used whale-oil soap (1 lb. to 7 gallons) with fairly good results." Mr. R. M. Palmer, of Victoria, B. C., says: "The Black Cherry Aphis was commoner than usual all through the lower portions of the province. It is, too, much more difficult to kill by means of sprays and is not so much attacked by parasites as other species. The quassia spray No 2, I found quite effective if used hot, as hot as the hand would bear; if used cold, only partially so." The spray referred to is given in the useful pamphlet "Insect Pests and Plant Diseases" issued by Mr. Palmer for the provincial Board of Horticulture and is as follows:—

Quassia chips	8 lbs.
Whale-oil soap	7 lbs.
Water	100 gallons.

"Boil the quassia chips in about 8 gallons of water for 1 hour; dissolve the soap in hot water; strain and mix both solutions together and dilute with sufficient water to make 100 gallons altogether. To be used with a spraying pump, with as much force as possible in applying. This mixture is the standard remedy for Hop Aphis, and has given most satisfactory results against other Aphides with no injury to the foliage of the trees treated."

THE APPLE APHIS (*Aphis mali*, Fab.), like the last named, was unusually prevalent at the time the apple trees were budding and caused much anxiety in Ontario, Quebec and Nova Scotia. The remedies which were recommended were whale-oil soap (1 lb. in 8 gallons of water) and kerosene emulsion (1 to 9); but fruit growers on a large scale were advised to wait until, at any rate, the middle of May, to see if the natural parasites did not reduce the plant-lice sufficiently to make remedies unnecessary. This recommendation I believe from experience to be safe for Ontario, but in British Columbia the Apple Aphis requires treatment as early as it shows itself, for in that province it is a far more injurious pest than in any other part of Canada. Dr. D. Young, of Adolphustown, Ont., during the course of some correspondence about an outbreak of Apple Aphis on his apple trees, writes:—

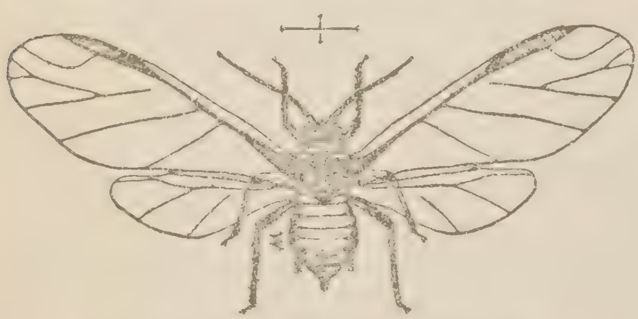

Fig. 21.—The Apple Aphis—enlarged.

"Adolphustown, April 20.—It would take about 270 sixty-gallon barrels of solution to spray my orchard, at 2 gallons per tree, so that I should need 1,065 gallons of kerosene and 266 lbs. of soap, besides the expense of labour. The tobacco spray would cost probably as much. I shall be glad to know whether you think it would pay me to spend a couple of hundred dollars in spraying for this pest or not."

In reply, Dr. Young was advised to wait a week or ten days, and if the plant lice did not increase perceptibly to do nothing beyond his regular spraying for Codling Moth and fungous diseases. Later in the season, I learned that this outbreak had passed away without doing serious harm to the crop.

The Bronze Apple-tree Weevil (*Magdalis ænescens*, Lec.).—Some specimens of apple boughs containing the young larvæ of this insect were received from Victoria, B.C., and Nanaimo, B.C. Mr. Palmer says of this insect :—" These small bark-borers, larvæ of *Magdalis ænescens*, continue to do much harm, especially in young orchards on dry lands of the Island. The lime, soap and carbolic acid wash is effective against them, if renewed at the end of May, but one application made early in spring has not proved sufficient. Many young trees were killed outright or so badly damaged that they will scarcely recover, where preventive measures were neglected."

From what I have seem of the injuries of this weevil, I am of the opinion that while the eggs are generally laid in trees which are in a feeble condition, at the same time they are also found in young and healthy apple trees. The attack by the beetles feeding upon the leaves of cherries noticed by Rev. G. W. Taylor on Gabriola Island last year was again noticed this season to a lesser extent, but appears to be a regular habit of the beetle. This might be taken advantage of for poisoning the mature insects as a means of reducing their numbers.

THE BLACK GOOSEBERRY-BORER

(*Xylocrius Agassizii*, Lec.).

Fig. 22.—The Black Gooseberry-borer : *a*, beetle ; *c*, *d*, larva ; *e*, pupa—enlarged.

One of the most interesting attacks which has come under my notice during the past season is by the extremely rare boring beetle (*Xylocrius Agassizii*), which may be called from the colour of the mature beetle and its habits, the Black Gooseberry-borer. The introduction of this insect into British Columbia, its detection and almost certain extermination by the Inspector of Fruit Pests, and also the successful rearing of the mature insect by Mr. E. A. Carew-Gibson are detailed in the following letters. It is hardly probable that this insect will ever become a serious pest of gooseberries, for it has been so extremely rare in the past that few collections possess specimens, while at the same time its probable native food plants, the various species of *Ribes*, are abundant on the Pacific slope.

" Victoria, B.C., March 1.—I am sending you by present opportunity under separate cover a box containing a bottle with borer grub and remains of roots of some young gooseberry bushes, which you will note have been hollowed out. Can you name this borer for me? I have not seen it nor heard of it before."—E. A. Carew-Gibson.

" Victoria, B.C., March 3.—I am sending you by same mail some specimens of roots of gooseberry bushes infested with a root borer, also a specimen borer in fluid. These plants came from Oregon last fall in a large consignment of plants, part of which —the younger bushes—are not infested, while many of the larger of older growth, are like those sent herewith. I am very glad indeed that the pest has been discovered soon enough to have the infested plants destroyed before the grubs mature, and I am busy now following up this work. I find that to detect the borer the roots must be snapped, which they do much easier than sound roots."—[R. M. Palmer.]

"Victoria, December 31.—In regard to the gooseberry bushes infested with larvæ of *Xylocrius Agassizii:* the plants were sent into the province from Oregon—shipped by the Oregon Wholesale Nursery Co., of Salem, to Victoria, in November, 1897. In all, 500 plants were condemned. These were a portion only of a shipment of

Fig. 23.—The Black Gooseberry-borer: infested stem—reduced ⅓.

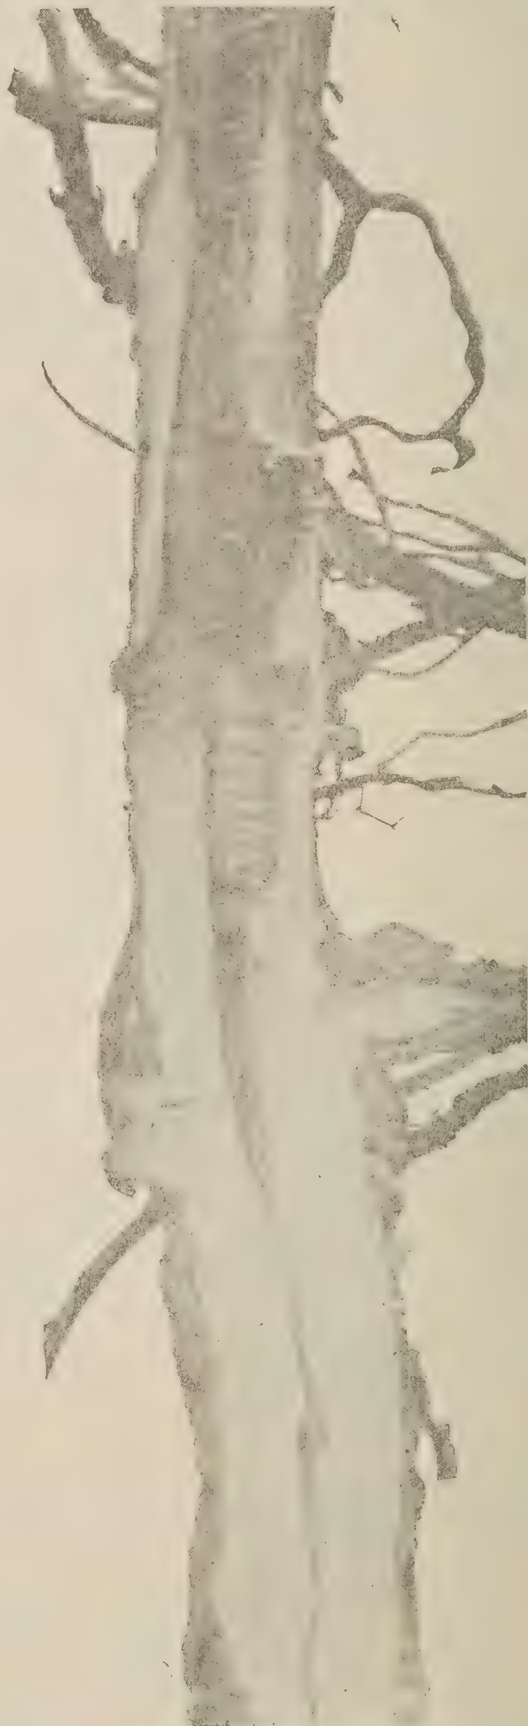

Fig. 24.—Larva in stem—slightly enlarged.

10,000 plants, and every package or bundle of the plants found to contain infested bushes was condemned and destroyed excepting only the specimens which were retained

for investigation, and some of which were forwarded to you. Upon referring the matter to the shippers of the plants, they stated that the stock was not grown by them, but bought from another nursery in their neighbourhood, and that the pest was altogether new to them. Mr. H. E. Dosch, of the Oregon State Board of Horticulture, also wrote in regard to the pest that he had not found it in Oregon in the course of his experience, which would indicate that its occurrence in Oregon as a fruit pest is, at least, unusual.

"I shall be glad to know where the borer belongs, and its usual food plants, if you can supply the information. I had supposed is was a species native to Oregon, and that it probably fed naturally upon indigenous plants.

"I feel quite safe in stating that there is no possible chance of any of the insects from this lot of plants having escaped destruction, but in view of the fact that large quantities of gooseberry bushes have been imported from Oregon for many years past, it is quite possible that it may exist in the province, and I propose to examine closely for it all plants which come under my observation. I am glad to say that Mr. E. A. C. Gibson has been successful in rearing mature specimens of the insect and is forwarding some to you as well as capital photographs of the larvæ and pupæ as they occurred in the plants.—[R. M. Palmer.]

In reply to an inquiry as to the occurrence of the Black Gooseberry-borer as an enemy of the gooseberry on the Pacific coast, Prof. A. B. Cordley, Entomologist of the State Agricultural College, at Corvallis, Oregon, writes: "The attack of *X. Agassizii*, which you describe, has never come under my notice, and I hardly think that this borer could have appeared in injurious numbers of late years in this State, or I should have heard of it."

Mr. Carew-Gibson, who by successfully carrying through to the perfect form three specimens of this very rare insect, has added one more to his triumphs in the investigation of the life-histories of insect pests, has forwarded to me the following notes upon this species:—

Notes on the Black Gooseberry-borer by Mr. E. A. Carew-Gibson.

The gooseberry bushes from which the specimens sent you were reared were brought into this province in a consignment of 500 two year old gooseberry bushes which came from the Oregon Wholesale Nursery Co., late in the fall of 1897. At the time of their importation no signs of the presence of the borers could be detected. The bushes were heeled in when received, and the damage done by the borers was first noticed in the spring of 1898, when the bushes were being planted out. Later on, after a thorough further examination, the whole of this consignment of 500 bushes was condemned by the Inspector of Fruit Pests and, except those bushes kept for experimental purposes, was destroyed under the inspector's direction. On inquiring from the Oregon Wholesale Nursery Co., it was ascertained that these bushes were not really their own stock, but had been bought from a neighbouring nursery to fill up the order.

The larva of which you can form a very fair idea both from the photo I send and from what you saw of them while here this summer, seems able to adapt itself very readily to its surroundings. I have now (31st December, 1898) a grub from the same lot of bushes which I took from a stem on 12th September, when it appeared to be full grown, and placed in a small glass phial tightly corked. It is still alive and wriggling; for the first two months it appeared undecided as to whether it would pupate without further food or not, later it began gnawing the cork of the phial, and it has now worked its way into the centre of the cork. One of the grubs pupated on 19th August (see photo) and the adult beetle appeared on the 18th day after, although at the time it was still soft. On opening another twig on 13th September I found another adult beetle apparently ready to emerge. There only appeared to be a single grub in each affected tree, and as the bushes were small this proved a very wise arrangement, as there would not have been room for more than one. The grub generally starts in from a convenient crotch somewhere about where the branches make a fork, it then works downwards, apparently wintering in the roots, in one case I noticed that it had worked so near to the soil that there must have been only the thinnest possible covering between it and the

soil, it then appears to work upwards in much the same way as the Raspberry Cane-borer, and after reaching some inches above ground, having first made a chamber with only the thinnest possible covering dividing it from the air, it pupates. I am sending you the only additional specimens I have for identification purposes, and these I take to be the larger the female, and the smaller the male; you will note considerable difference in their size. I caged these two beetles on a living bush inside a large glass on my table on 14th September; on the 15th I found an egg resting in the crotch formed by a thorn on one of the twigs, but I lost this egg while examining it under the microscope; it was very small and had its surface beautifully ornamented. 21st September, female apparently dying, male still very active. 22nd, female dead; on the 27th the male was still strong. I could discover no more eggs.

E. A. Carew-Gibson.

The specimens of the beetles sent by Mr. Carew-Gibson proved to be two females and a male of the rare longicorn bettle above-named. I am indebted to Mr. W. H. Harrington and Dr. L. O. Howard for the exact identification of the species. Through the courtesy of Dr. Howard also, the beautiful figure 22 given above has been specially drawn for this report by Miss L. Sullivan, the accomplished Artist of the Division of Entomology, at Washington, D.C, under the supervision of Mr. F. H. Chittenden of the same Division. Figures 23 and 24 are from photographs by Mr. Carew-Gibson.

The genus *Xylocrius* is characterized as follows by Leng in the *Bulletin* of the Brooklyn Entomological Society, vol. VII., p. 113.

"*Xylocrius*, Lec.—This genus presents another remarkable form. The antennæ are very stout, quite hairy, the thorax very convex and rounded at the sides, the elytra constricted behind the base and strongly rounded at tip, and the entire surface deeply punctured and pubescent. Two species have been distinguished:—

More slender; elytral punctures before middle gross, somewhat confluent, surface shining; behind middle, punctures finer, surface opaque.......... *Agassizii.*
More robust; surface all shining; punctures large, foveate, irregular, more or less confluent....... ....*cribratus.*

"*X. Agassizii*, Lec. (*Proc. Ac. Phil.*, 1861, p. 357)—The hair behind the middle of elytra is more dense; 3rd and 4th joints of antennæ about equal. Length, ·45 inch =12 mm. Habitat: California.

"*X. cribratus*, Lec. (S. M. C., 1873, No. 247, XI., p. 172).—Pubescence equal throughout; 3rd joint of antennæ one-half longer than 4th. Length, ·55 inch=15 mm. Habitat: California, Nevada."

The following description was made from the three specimens sent by Mr. Carew-Gibson:—Length, male, $\frac{3}{8}$ inch; female, $\frac{1}{2}$ inch. Colour, deep dull black; whole body covered with downy, rather sparse, pubescence; erect bristles on head and thorax; elytra slightly constricted in the middle; thorax and humeral half of elytra coarsely punctate; apical half, velvety, silky, opaque; abdomen of male shiny black, of female piceous; antennæ rather short and stout, of about the same length in both sexes; thighs swollen in both sexes; general appearance between *Asemum* and *Callidium.*

SPRAYING.

From every province overwhelming evidence proves the very great value of spraying fruit trees for the prevention of damage by both injurious insects and fungi. Owing to the large amount of capital invested in fruit farms and the permanent nature of the plantations, a great deal more attention has been devoted to the enemies of fruits than to those of any of the other ordinary crops which occupy the land for only one or two years, or even less. The consequence is that the habits of these pests are pretty well understood and standard practical remedies have been devised for most of them. These have been made known widely by means of official reports, agricultural periodicals and the daily press.

Up-to-date fruit growers know well the advantages they derive from attending carefully to the work of spraying their crops. It is very seldom now-a-days that one hears from practical business men engaged in fruit growing the childish, illogical excuse that they have not "had time" to spray their trees, as these men know well that "spraying trees" and "making money" are almost synonymous terms. There are now to be had free for the asking in Canada publications setting forth the advantages of spraying and giving full instructions as to the best way to prepare and apply simple, cheap and effective remedies for almost any insect or fungous disease that is likely to be found injuring orchard crops. Indeed, to those who have thought upon this subject it may seem unnecessary to again draw attention to this matter in an official report; but in travelling through Canada, notwithstanding the fact that many of the provinces have able and enthusiastic officers who are doing their utmost to teach farmers the great benefits which they may derive from this simple method of protecting their crops, I find that there are thousands of fruit growers everywhere who have never had enterprise enough to follow the advice given. Knowing well, after many years study of this subject, what enormous saving may be made for the whole Dominion through the sure advancement of every individual, I again draw attention to some statements by reliable men, which I trust may have the effect of persuading more of our Canadian fruit growers and farmers that *spraying does most decidedly pay*, and, as far as I have seen, successes follow intelligent, careful and conscientious effort, much more surely in the case of spraying fruit trees than in any other branch of agriculture or of most other walks of life.

"Much loss has heen caused by insect pests. The apple crop in particular suffered much from worms in unsprayed orchards." (*Ontario Crop Report*, Nov., 1898.)

"Wolfville, N.S., Dec, 1898.—Cankerworms have been less abundant this year than usual, but some orchards in Grand Pré and Avonport were stripped. Where spraying was practised, very little damage was done.

"Spraying with Bordeaux mixture and Paris green combined is now generally practised by most of our best fruit growers, both before and after blossoming. They know that it pays them to do so, and is necessary if they are to secure fruit which will bring the highest price. The methods, however, are evidently not as yet thoroughly understood; for some varieties of apples have been somewhat injured in appearance this year, *i. e.*, they are russeted by a too strong solution, or perhaps too frequent applications; but practice and experience will soon give the necessary skill to get the happy medium between over and under dosing."—[R. W. Starr.]

"The day of good crops of fair apples, *without effort*, is for ever gone, unless conditions change greatly, but the prospects were never higher for the pains-taking, thorough orchardist. If any one needs a full, conclusive, and final demonstration that spraying is a necessary part of apple culture, let him look at almost any unsprayed orchard, then compare it with any sprayed orchard which he may find. If he does not see the difference, if he cannot find evidence that spraying has paid 500 to 1,000 per cent, it will be because he is not open for conviction." (Extract from *Report American Pomological Society*, in Nova Scotia *Crop Report* for November, 1898.)

"Victoria, B. C.—Most of the pests and diseases of fruit trees found here have been successfully dealt with by simple remedies which have been recommended through Bulletins and Reports. Enormous advantage has followed the adoption of spraying, and the feeling of uncertainty as to their success which certainly existed at one time in the minds of many of our fruit growers, is gradually being removed. Those who attend to their business properly are, as a rule, well satisfied."—[R. M. Palmer, Provincial Inspector of Fruit Pests.]

In this connection, special attention may be drawn to the series of spraying experiments which have been carried on during the last four years by instruction of the Hon. John Dryden, Provincial Minister of Agriculture and Arts of Ontario. These experiments were at first supervised by Mr. A. H. Pettit, of Grimsby, Ont., and for the last three years by Mr. W. M. Orr, of Fruitland, Ont. A great many orchards in all parts of the province have been sprayed under the personal supervision of the inspector. Fruit growers in the different districts have been invited to be present at these demons-

trations and receive instruction in the way to prepare the materials and apply them. At the last Industrial Fair held at Toronto in September, 1898, one of the most instructive exhibits was undoubtedly the display of fruit taken from sprayed and unsprayed trees in the same orchard. In this collection, which attracted naturally much attention, there were exhibited about 250 plates of fruit from 24 different localities, those from sprayed and unsprayed trees being placed in separately side by side for easy comparison. The fruit was sent in by the owners of the different orchards where the experiments had been carried out, and was not seen by the inspector until they arrived in Toronto, to be arranged and placed on exhibit.

In a most interesting report upon these experiments which was read by Mr. Orr, at the last meeting of the Fruit Growers' Association of Ontario, held at St. Catharines, Ont., in December, he stated that this year he had worked at 30 points covering the province from Amherstburg to Renfrew. The agents visited each point seven times and his dates were announced by poster, postal card and in the press, so that as many as possible might know when these experiments were to be carried on. That the farmers appreciated this effort of the Ontario Government to benefit them and demonstrate to them the best methods of caring for their orchards, is shown by the fact that over 3,500 attended, besides many who visited the orchards at other times when the agents were not there. This is almost double the number who attended two years ago. There was always kept on hand a good supply of the spraying bulletin issued by the Ontario Government which had been revised and brought up to date, and a copy was given to all who wished to receive it. Work was simplified as much as possible, only one solution being used, viz., the ordinary Bordeaux mixture and Paris green, of the strength advised for orchard use: Copper sulphate 4 lbs., fresh lime 4 lbs., and water 40 gallons, Paris green 4 ounces. Notwithstanding the fact that on account of the law which forbids the spraying of fruit trees when in full bloom, and on account of inopportune rains, many applications were lost, as it was necessary to do the work upon the exact dates and at the hours advertised, so that the agent might keep his engagement at the next point he was due at, the results on the whole were most satisfactory, as is clearly indicated by the enthusiasm of some of the orchard owners on whose trees the experiments were carried out. In estimating the percentage of perfect apples, a part of each tree was picked clean and the fruit was carefully examined, every specimen which had a worm or a spot, no matter how small, being rejected as imperfect. This report will be published in full by the Fruit Growers' Association of Ontario, and will contain the reports of the individual owners of the orchards. In concluding his report, Mr. Orr, who is a practical fruit grower, says: "It appears from results obtained in experimental work that from 65 to 80 per cent of perfect fruit can be secured when spraying is regularly and properly done and when the conditions are favourable."

It is perhaps not worth while now devoting more space to this subject; the facts are well known and taken advantage of by all enterprising horticulturists who keep themselves posted on all the subjects which materially affect the profits of their labours. Those who do not know and do not by spraying save every year more than 25 per cent of nearly every crop they grow from the ravages of their many insects and fungous foes, at any rate have not the excuse that they have not had every opportunity of learning.

Every year, as the time for spraying and otherwise treating crop plants comes round, horticultural publications and the weekly and daily press contain articles giving the experience of practical men who have tried these methods and at the same time full advice as to the best way of carrying on the work.

THE APIARY.

I submit herewith Mr. John Fixter's report as manager of the apiary. This branch of the work has been left entirely in Mr. Fixter's hands. It must be attributed to his good management and skill that the bee department this year has become so popular. Meetings of bee-keepers were addressed by Mr. Fixter, at the following places:—Duncanville, Bell's Corners, Merivale, Rockland, and Bearbrook, all in the Ottawa district.

The season for bee-keepers has been a remarkably good one. The clover crop was better than has been seen for many years in Ontario and Quebec, and all shrubs bloomed profusely in early spring.

REPORT OF MR. JOHN FIXTER.

Experiments in Wintering, 1897–98.

The following seven experiments have been tried: Four were tried in the cellar (Nos. 1, 2, 6 and 7), one in a root-house (No. 3), one in a pit dug in a hill side (No. 4), and another in the House Apiary (No. 5).

The cellar is below a private house. The walls are stone and the floor cement. The bee-room, 11 feet 6 inches wide by 15 feet long and 7 feet high, allows three tiers of shelves and two passages. It is boarded off from the remainder of the cellar by a partition which extends all around the chamber, and far enough from the stone wall to allow of a small air space. Under the cement floor a layer of small stones 8 inches thick acts as a drain and keeps the cellar perfectly dry. The lowest shelf is 18 inches from the floor, the second 20 inches in the clear above, and the third 20 inches above that. Neither the hives on the third shelf nor the uprights supporting the shelves touch the ceiling, so that no vibration can reach the hives from the ceiling. This chamber is thoroughly ventilated, also the whole cellar. There is a three inch pipe passing through the bee chamber up to a stove pipe provided with a damper with which to regulate the draught.

Before entering the bee-room is a smaller room with a door leading outside and another leading to the bee-room; both rooms are provided with sliding ventilators, so that outside air may be let in at will. Ventilation is carefully attended to and sudden changes of temperature are avoided; for this, a thermometer which is always kept in the cellar, is watched. The best temperature for the bee cellar has been found to be from 42 to 46 degrees Fahrenheit.

This arrangement has given entire satisfaction. In former years there was not proper ventilation, and the cellar was always damp. Since the concrete floor has been laid and the ventilators put in, the cellar has been much drier and cleaner. It is also rat and mouse proof, which is a very great advantage. The difference in the consumption of honey by the bees is marked, the quantity being now only half what it was before the cellar was improved. The coal stove which was formerly in the smaller room to keep a uniform temperature and to keep the cellar dry, has been abandoned, as the cellar and hives can be managed so as not to require it. I would not recommend any one to use artificial heat.

Experiment No. 1.—Eight colonies were put into winter quarters in the cellar and placed on the shelves. Under the back end of each hive was placed a three-inch block, by which means the back of each hive was raised so as to insure free ventilation. Each hive was besides raised from its own bottom board by a small three-eighths of an inch block placed at the back. All front entrances were left wide open, the wooden covers all removed, and replaced with cushions made of chaff 4 inches thick, and wide and long enough to lap over the hive 2 inches.

Temperature was taken once a week all through the winter:

November, 46 to 47 degrees.	February, 46 to 50 degrees.
December, 47 to 48 "	March, 48 "
January, 44 to 46 "	

The bees were quiet, only a very slight hum being noticeable up to February, when, the temperature having risen to 50, the bees began to get uneasy and make considerable hum. Cold air was carefully let in during the night by opening the slides in the doors at night and closing them in the morning; this lowered the temperature and the bees quieted down. During the past winter every colony in this experiment was perfectly dry and clean, and all came out in excellent condition.

Average weight of each hive when put into winter quarters, 53½ pounds; when taken out on 26th March, 44½ pounds per hive, showing that each hive had lost 9 pounds on the average, which is very much less than the usual amount. This small amount is owing to the comfortable cellar. In former years, before this same cellar was arranged as it is, the hives lost on an average 20 pounds, which represented the weight of honey consumed during the winter.

Experiment No. 2.—Two colonies were put into the cellar on 12th November, with tops and bottoms of the hives left on, just as they were brought in from the bee-yard. They were watched for dampness, and to compare the amount of honey consumed. Temperature of cellar the same as in No. 1. During December and January both hives made considerable hum. 27th December, drops of water were noticed all along the entrance of both hives. This same trouble continued in January, when they were both given more ventilation at the bottom by a three-inch block being placed in front between the bottom board and the brood chamber. During February and March both hives got perfectly dry and quiet. 26th March, both hives were removed to their summer stands in fairly good condition; one had spots of fæces on the entrances; both hives were damp and the combs were slightly mouldy, but there were very few dead bees in either hive. Average weight of each hive when put into winter quarters, 62½ pounds; when taken out on 26th March, 48 pounds, showing that each hive had lost 14½ pounds per hive. Another examination was made on 23rd April, when both were found building up rapidly as the season was favourable. 21st May, both in excellent condition for a honey flow.

Experiment No. 3.—Two colonies stored in a root-house. The hives were placed on a shelf nailed up against the wall, about 3 feet from the ceiling and projecting 2 feet. A curtain was hung from the wall over the top and down in front of the hives so as to keep out all light; wooden covers removed and replaced with a chaff cushion. A strip of wood 2 by 2 inches was placed all along both sides between the brood-chamber and the bottom board, so as to give more ventilation at the bottom, both back and front were left wide open. In former years the hives kept in the root-house did not appear to have ventilation enough; this extra space has proved very satisfactory. Temperature was taken every Monday of each week. November, highest temperature, 38, lowest 36; both hives quite dry but very noisy. December, highest temperature, 42, lowest 36; both colonies were very noisy, but were perfectly dry; mice had found their way into both hives and disturbed the bees; some strips of tin put around prevented them getting in again. January, highest temperature, 41, lowest, 39; during January, both hives had drops of water along the entrance and were making considerable sound; no trouble from mice this month. February, temperature 38 to 39, both hives were very much drier, and by the end of the month they were perfectly dry and fairly quiet. March, highest temperature 40, lowest 36, both hives were very noisy and quite damp. 26th March: Both hives removed to bee-yard. Both colonies showed signs of dysentery, dampness and mould, but were very strong in numbers.

Average weight of each hive when put in in autumn of 1897, 57 pounds, 12 ounces; spring 1898, 44 pounds, 12 ounces; a loss of 13 pounds. On 23rd April another examination was made. Both hives were building up and in excellent condition for a honey flow.

Experiment No. 4.—November 12. Two colonies were put into a pit dug in the side of a hill, 3 feet deep, 3 feet wide, and 10 feet long, in such a way that the ventilators

at both ends might not be immediately above the hives, which were in the middle of the pit. The hives rested on two cedar poles laid along the full length of the pit. The ventilators, which were 3 inches by 4 inches, were made of boards, three of which reached down to the bottom of the pit, the fourth only to the top of the pit, and the ventilators rose 3 feet above the ground, wooden covers removed and replaced by chaff cushions. In each hive 2 by 2 inch strips of wood were laid under both sides and under the back end between the brood chambers and the bottom boards, so as to provide more space at the bottom of the hive in case a quantity of dead bees should accumulate there. The pit was covered with cedar poles laid along its length, the middle ones higher than the others, and these covered with a layer of straw and one foot of soil. A small shaft was also arranged between the hives, down which a thermometer could be lowered by means of a string, so that the temperature of the pit could be ascertained Temperature was taken once each week. From November to March the temperature did not go below 38 nor above 39. On 26th March the pit was opened, when it was found that water had got in and risen half way up the hives, both colonies appeared to be fairly strong in numbers, combs were badly moulded. On 5th April one hive was noticed to be very weak. On 23rd April it was deserted. The other hive came through well, and on 23rd April was building up rapidly.

This experiment did not come out as well as in former years, owing to the water getting into the pit. This water came from a trench dug above the pit, with no outlet but into the pit. There was no trench dug in former years and no water had troubled.

It will also be noticed no straw was put in the pit over and around the hives as in former years. We find it much better without any straw. Weight of each hive in the autumn of 1897, 62 pounds, and in the spring of 1898, 50 pounds 6 oz., a loss of 11 pounds 10 oz. each.

Experiment No. 5.—Wintering in House Apiary.

Two colonies Nos. 47 and 48, were left in the house apiary with some additional packing. The House Apiary faces the south, the walls are double boarded, with an air space of four inches. The floor, which is about one foot from the ground is also double boarded and there is no draught under it. The hives were moved one foot from the wall, and placed on a double thickness of sacks laid on the floor; the wooden covers were removed and replaced by chaff cushions. In addition to this, the hives were covered above and all around with a double thickness of the same sacking. Also 1 foot of cut straw was put below and all around. A small shaft 1½ inch square extended from the opening of each hive to the outside of the shed; 2 inch strips of wood were placed under both sides and under the back, between the bottom board and the brood chamber, so as to give more space at the bottom of the hive in case a quantity of dead bees should accumulate.

No flying took place from 12th November, 1897, until 7th March, 1898, when several bees flew out but were not seen to return. On 8th March they were flying briskly going out and returning. From 8th March to 26th they flew 9 days.

On 26th March they were unpacked: Hive No. 47 had 2 inches of dead bees on the bottom board and was in a very weak condition. Hive No. 48 also had 1 inch of dead bees on the bottom board but appeared to be in better condition than No. 47.

Another examination was made on 21st April, when hive No. 47 was found to be deserted, the combs were quite dry and clean and there was plenty of sealed honey in the hive.

Hive No. 47 weighed in the autumn of 1897, 54 pounds, and in the following spring 34½ pounds, showing a loss of 19½ pounds. Hive No. 48 weighed in the autumn of 1897, 56 pounds, and in the following spring 39½ pounds, a loss of 16½ pounds.

Experiment No. 6.—Two colonies were put into the cellar with bottoms of the hives left on, just as they were brought in from the bee-yard. The wooden covers were removed and nothing left on except a tightly sealed propolis quilt, the entrance was left wide open. During the entire winter the bees kept perfectly dry, and very slight hum could be heard.

March 26th.—Both hives removed to bee-yard; appeared to be in excellent condition; there were scarcely any dead bees and the hives were dry and clean.

Total weight of the two hives when put in, 104½ pounds; when taken out, 83 pounds, a loss of 10 pounds 12 oz. each. Another examination was made 21st April, when they were both found to be building up rapidly and in excellent condition for a honey flow.

Experiment No. 7.—Two colonies were put in the cellar and placed on the shelves, a three inch block being placed between the bottom board and the brood-chamber only *in front*, making the full entrance 3 inches high across the whole front. The wooden covers were removed and replaced with a chaff cushion. Temperature same as No. 1.

During the whole winter both colonies in this experiment were perfectly dry and clean and showed no uneasiness of any kind. They came out in the spring in excellent condition.

Average weight of each hive when put into winter quarters 58¼ pounds; when taken out on 26th March, 47 pounds 10 ounces, showing that each hive had lost 10 pounds 10 ounces.

Conclusions.

Experiment No. 1.—Has given entire satisfaction for the past four years. The amount of honey consumed during the winters per colony was in 1894-95, 12 pounds 9 ounces; in 1895-96, 10 pounds; in 1896-97, 9 pounds 6 ounces; 1897-98, 9 pounds; or an average for the four years, 10 pounds per colony.

Experiment No. 2.—Hives put in the cellar as they came from the bee-yard had not sufficient ventilation. This result agrees with that of the past three winters.

The amount of honey consumed during three winters was: 1895 to 1896, 13 pounds per colony; 1896 to 1897, 11 pounds 8 ounces; 1897 to 1898, 14 pounds 8 ounces; or an average for the three years of 12 pounds 13⅓ ounces each. Although the amount of honey consumed is not large, the vitality of the bees was not as good as in several of the other experiments tried.

Experiment No. 3.—Wintering in a root-house. This experiment was again fairly satisfactory; although an extra space of 2 inches was given at the bottom, the hives were damp and mouldy. Considering the amount of disturbance the bees are subject to in this experiment, I would consider they came out well.

Once or twice each week the large doors of the root-house were thrown wide open to allow the teams in to draw the roots out, and this let in much cold air which came suddenly upon the hives; also the teams, drawing over the floor, jar them very much. The amount of honey consumed per colony was in 1896-97, 14 pounds, and in 1897-98, 14½ pounds.

Experiment No. 4.—Wintering in a pit dug in a dry hill side. This experiment has been very satisfactory. The past year a misfortune happened; when covering the pit a trench was dug in such a way that water could not run out of it and finally got into the pit. The amount of honey consumed per colony in 1896-97 was 9 pounds, in 1897-98, 11 pounds 10 ounces.

Experiment No. 5.—Wintering in a House Apiary. This experiment was again a failure. The extra packing with 1 foot of cut straw was not sufficient to keep out the cold. I would not advise any one where the temperature reaches 15 below zero to winter in a house apiary such as described in No. 5 experiment.

The amount of honey consumed per colony during the winter of 1896-97 was 15½ pounds, and in 1897-98 16½ pounds. This shows a larger amount consumed; the condition of the bees when taken out in the spring was besides very weak. The colonies either dwindled out or did very little good the following summer.

None of our experiments in wintering out of doors have given the same satisfaction as those in the cellar, even when extra packing was given.

Experiment No. 6.—Hives put in the cellar as they came from the bee-yard, excepting that the wooden covers were removed, leaving on only the thick propolis quilt. This mode of wintering has given satisfaction the past winter but will be tried further.

Experiment No. 7.—Hives in the cellar raised in front only so as to give very wide opening for ventilation. This experiment was also satisfactory and will be further tried.

SEASON OF 1898.

March 9th being a warm, sunny day, twelve colonies were removed from their winter quarters: six were placed in the House Apiary, and the other six in the exposed apiary, where the snow was about eighteen inches deep. All began to fly at once, and the snow soon became very much spotted with fæces, but there were very few dead bees around the entrances of the hives. The hives in the exposed apiary were covered with coarse sacks as a protection, leaving a very small entrance for the bees. In the House Apiary no such protection was given. From 9th to 26th March the bees flew eight days. The remaining colonies were taken out on 26th March.

From 26th March to 9th April the bees flew five days. On 9th April the first pollen was noticed to be gathered. From 9th to 27th April they gathered pollen very freely off soft maple and willows, also off the Manitoba maple. They were seen gathering sap from hard maples, wherever the trees were cut. On 27th April, a very fine and warm day, all colonies were inspected. Any that were found short of stores were fed with warm syrup. For this an empty frame was taken out and held slightly slanting, the syrup was poured on the empty comb until every cell was filled, then the frame was returned to the hive. This plan of feeding answers very well for spring, but not for autumn feeding. The first new honey was noticed on 1st May. Up to 1st May the bees in the house and sheltered apiaries appeared to work better than those in the exposed apiary. On many days when the weather was cool, they were flying well, while none of the others were flying. Those set out early appeared to be in the best condition, as they had several cleansing flights before the others were set out.

May was very fine and warm. The bees worked unusually well, gathering honey and pollen from maples, apple, plum, cherries, Siberian pea-tree, buckthorn, and also from dandelions, buttercups, white and alsike clovers. On 27th May two fine swarms came off; one from the house apiary, and one from the sheltered apiary. Supers were put on all the hives which were full of bees. Many at once began to work in them.

June was very favourable for the bees to work, white and alsike clover being abundant, very much honey was stored in the supers.

July 4th, all supers containing clover honey were removed to a warm room, where the temperature was not lower than 65°. We have found by experience that honey kept in a cool or damp room does not ripen properly. The basswood was just then coming into bloom; the bees gathered considerable honey from it up to 20th July. The supers containing basswood honey were removed on 25 July, as the buckwheat was then beginning to bloom.

On 3rd August when the buckwheat was ploughed under as a fertilizer, the bees had already gathered much honey from it. From 3rd to 18th August the bees were working well on the second growth of alsike and Bokhara clovers. On 18th August all supers were removed, and any honey gathered after that date was left for winter stores. All the colonies were carefully examined at this date to see if they were good and strong, and had a good laying queen. Several were found queenless, and were at once supplied with young queens. It is very important to see that there are no caterpillars of bee-moths around or in the hives. If any traces of moths are noticed these should be cut out at once, and the hives examined at short intervals afterwards.

September 1st to 12th the weather was fine and warm; there was considerable flying. All the hives were weighed, and any that did not weigh over 50 pounds were given full frames of sealed honey. The beginning of September is a good time to inspect winter stores. If syrup has to be fed, the bees will take it down better when the weather is warm, and will thus have a chance to seal it over, which is very important for wintering. But rather than feed syrup to the bees, I would strongly advise every bee-keeper, unless he is thoroughly experienced, to save a few frames of sealed honey in case his bees have not enough to carry them through the winter. He will find it to his advantage to place one or two full frames in the hive in preference to feeding syrup. Feeding syrup to the bees in the autumn gives them a tendency to rob. A good receipt for bee syrup is the following: Boil the water, then remove it from the stove, add at once two parts of granulated sugar to one part of water (by weight) and stir until dis-

solved. It may then be fed to the bees moderately warm in the evening. The old method of dissolving the sugar while the boiler is on the stove is unadvisable as the sugar is liable to be burnt, which would be harmful to the bees.

In order to secure a provision of frames filled with syrup, the best way is to get the strongest colonies to fill and seal them. For this purpose an extracting super is placed on the top of a strong colony, to which syrup is then fed. The bees will then work and fill the frames in the super with syrup. When the frames are filled they are removed and afterwards given to the colonies that require to be fed. If weak colonies were fed in many cases they would be robbed by the stronger ones.

Experiments with Foundations of Different Sizes in the Sections.

There were two objects in view in these experiments. One was to find out which size of foundation the bees would start to work on first; second, to find out which sections would be filled best and have the fewest empty cells around the sections. Several supers were used having the sections so arranged that all would have an equal chance of being filled.

Experiment No. 1: sections with full sheets of foundation fastened on top only. Experiment No. 2: sections with half sheets of foundation fastened on top, and experiment No 3: one inch square of foundation fastened on top in the centre.

In every instance, the bees worked first on the full sheet, and these sections when finished had the fewest holes or empty spaces around them. In the sections which had half sheets of foundation the bees did not work as soon as on the former ones, and the sections were not so well filled. The sections which had one inch square of foundation sheets attached to the top were the last worked on. They also had most vacant spaces around the sections. These experiments should be tried again, also others with pieces of foundation attached at different points around the sections.

House Apiary.

The House Apiary was again tried, and in 1898 to a greater extent than former years. Two tiers of hives have been put in, one on the floor which is one foot from the ground. The second tier was set on a shelf 3 ft. 6 inches from the floor. This plan can be safely recommended for cities or towns where space is scarce, and two tiers can be arranged as well as one in the same building. It has many advantages for the summer, but fails for the winter. See former reports.

Returns.

The past season has been a very good one. The returns of the Central Experimental Farm Apiary for the season of 1898 show an average of 78 sections per colony. The colonies which were run for extracted honey gave 94½ pounds per colony.

Swarming for the season on the whole has been satisfactory. Colonies should not be allowed to give more than one swarm in a season. Excessive swarming may be prevented by the following method: As soon as a colony swarms out and the swarm is well settled, hive it. Remove the hive that it came out of to another stand, then place the new hive on the old stand. Many of the workers returning from the field will help to build up the new colony. If the old colony is found to be still very strong take out two or three frames and shake the bees off in front of the newly hived swarm. This will weaken the old colony and prevent it from swarming again. You will then have a good strong swarm in the best shape for gathering honey.

JOHN FIXTER.

FARM STOCK.

THE HORN-FLY (*Hæmatobia serrata*, Rob.-Desv.).—In the provinces of Ontario and Quebec the Horn-fly was reported as being slightly more troublesome than last year. This was also the case in some places in Nova Scotia, but at most places the annoyance was less. In Prince Edward Island, where this year it was expected to give more trouble than elsewhere, Father Burke writes from Alberton, P.E.I.: "The Horn-fly was not so bad early in the season as in other years, as the wet weather was fatal to the larvæ, but later it was a troublesome pest and, I feel sure, was as numerous as in its first years here. People did not oil so systematically or persistently, and this may have been the cause. I do not think that any effort is being made to disturb the cattle droppings in the fields where the flies breed."

Remedies.—These consist of applying to the animals some oily substance obnoxious to the flies to prevent them from biting. Of many kinds tried, Mr. Robert Elliot, the Herdsman at the Central Experimental Farm, has for 2 or 3 years used when necessary a mixture of 1 pound of pine tar in 10 pounds of lard, and still finds it the most convenient and effective remedy.

Regularly spreading out the fresh cattle droppings in the field with a rake, so that they dry up and become unfit for the maggots to breed in, has been found an easy and useful remedy. The eggs are laid by the flies at once on fresh droppings, and if these are disturbed every other day in the favourite places in pastures where the cattle congregate, large numbers of the larvæ are destroyed.

REPORT OF THE POULTRY MANAGER.

(A. G. GILBERT.)

To Dr. WM. SAUNDERS,
Director Dominion Experimental Farms,
Ottawa.

SIR,—I have the pleasure to submit to you the eleventh annual report of the Poultry Department.

The operations of the year are explained in detail. It is gratifying to note that notwithstanding the reduction in daily rations from three to two, made the year previous, there was an increase in the number of eggs laid last winter season, the period of high prices, and which was one of the objects aimed at. Experience shows that the obtaining of eggs in winter, in the colder districts of the Dominion, is an exact science. If too much, or too stimulating food is given, disaster follows. If the rations are too stinted, there is no satisfactory result.

As further experience is gained, there is every reason to hope for still better results, at further reduced cost.

It is worthy of remark that notwithstanding the increased number of eggs laid by the hens of the farmers and the large quantities held over, in cold storage, that the prices in late fall and early winter, in Ottawa and Montreal, were little, if at all, affected. A letter received from Mr. Walter Paul, a leading grocer in Montreal, by the writer, reads as follows :—

"MONTREAL, 18th Dec., 1898.

"DEAR SIR,—Your favour of 16th instant received. I am getting lots of fresh eggs. I am paying 40 cents per dozen here for the best. They are all fresh from farmers. I will not take any eggs from storekeepers. I get eggs from as far west as Chatham, Guelph, Cobourg, Belleville, &c.

"Yours truly,

WALTER PAUL."

Mr. W. J. Wilson, poultry breeder, Amherst Park, Montreal, writes: "I am receiving 40 cents per dozen just now for all the eggs I can get."

The price in Ottawa, at the same time, to farmers was 35 cents per dozen.

Prices such as quoted offer a large margin of profit to farmers, who will doubtless be most interested in the details given in report herewith, as to the composition and effect of the less bulky and costly ration.

I have to acknowledge the present of 16 Pekin duck eggs from Mr. A. Thompson, the well-known breeder of Allan's Corners, Que., also a setting of Buff Leghorn from C. R. Frith, Esq., M.D., of Winchester, Ont.

During the year addresses were delivered at the following points :—

London, Peterborough, Owen Sound, Cobourg, Baltimore, Pakenham, Madoc (2), Perth and Smith's Falls. At the first four places named, displays of dressed poultry were made.

It affords me pleasure to again remark on the faithful and zealous discharge of his duties by Mr. George Deavey, to whose intelligent manipulation of the rations so much of the success in the winter production of eggs is due.

I have the honour to be, sir,
Your obedient servant,

A. G. GILBERT.

REPORT ON THE WORK OF 1898.

The work of the past year may be said to have been to a great extent confirmatory of that of the previous one. It is important that it should have been so, for at the beginning of the winter of 1896-97, the rations had been reduced to two *per diem.* While the results were gratifying, it yet remained for the experience of another year to confirm or modify the data then obtained and given in detail in report of last year, 1897. The experience of the past year confirms the beneficial results following the reduction of the rations to two in number. It has also shown that under favourable conditions, such as cheaper price of grain and still further reduction in kind and bulk of rations, it is possible to yet reduce the cost of the daily rations. Indeed this reduction in cost would have been secured last year, but for the increased price of wheat from one cent to one cent and a quarter per pound, and the cost of cut bone from one to one cent and a half per pound. It being remembered that the object is always to have eggs during the winter season, the period of high prices, in as great quantity and at as little cost as possible. It will be interesting then to note :—

1.—The difference in the winter rations of 1896-97 and 1897-98.
2.—The egg yields of the two years so as to permit of comparison.

THE DIFFERENCE IN THE COMPOSITION OF THE TWO RATIONS.

First we take the daily rations for the winter of 1896-97 (the winter before last), which was made up as follows :—

20 pounds wheat, or buckwheat, at 1 cent per pound..........	20
18 do cut green bone, do	18
Grit and vegetables....................................	03
	41c.

The above was fed to 151 hens and 53 pullets, a total of 204.

The feeding of winter rations generally commenced about the beginning of November, sometimes earlier.

The ration was varied by the feeding of warm mash about 3 time per week in lieu of the cut bone. The mash was composed of ground grains in such quantity as not to exceed the value of 18 cents.

THE RATION OF LAST WINTER.

Before giving the composition of the new ration some explanation, as to the manner in which it differed from its predecessor, is necessary. It principally differed in being divided into two parts, viz. :—

Part 1.—For hens one year of age and over.
" 2.—For pullets.

The division was considered necessary, for the reason, that the experience of previous winters had led to the conclusion that the pullets would stand more food and, perhaps, lay better, while the same quantity, if given to older hens would tend to make them so fat as to lay few, if any eggs. The pullets accordingly received more food—were

forced a little more—in the shape of a small quantity of mash every day, while the older hens received it only occasionally. The rations of last winter 1897-98, were composed as follows:—

PART I.—FOR 157 HENS OVER 1 YEAR OF AGE.

10 pounds wheat at $1\frac{1}{4}$ cents per pound		$12\frac{1}{2}$
$1\frac{1}{2}$ " oats at 1 cent per pound		$1\frac{1}{2}$
Grit and vegetables		$1\frac{1}{2}$
Mash composed of—		
Shorts, 3 pounds at 1 cent per pound	3	
Cornmeal, 2 pounds at $1\frac{1}{2}$ cents per pound	3	
Ground oats, 3 pounds at 1 cent "	3	
Small potatoes, 2 pounds at $\frac{1}{4}$ cent per pound	$\frac{1}{2}$	
Blood meal, 1 pound 4 oz. at 3 cents per pound	4	
	—	$13\frac{1}{2}$
		29

Another day 10 pounds of cut bone would take the place of the mash when the ration would be as follows:—

Cut bone 10 pounds at $1\frac{1}{2}$ cents per pound	15
Wheat 10 pounds at $1\frac{1}{4}$ "	$12\frac{1}{2}$
Grit and vegetables	$1\frac{1}{2}$
	29

PART II.—FOR 63 PULLETS.

Wheat, 5 pounds at $1\frac{1}{4}$ cents per pound		$6\frac{1}{4}$
Mash composed as follows:—		
Shorts, 2 pounds at 1 cent per pound	2	
Cornmeal, 2 pounds at $1\frac{1}{2}$ cents per pound	3	
Small potatoes, 4 pounds at $\frac{1}{4}$ cent per pound	1	
	—	6
Grit and vegetables		$1\frac{1}{2}$
		$13\frac{3}{4}$

When cut bone was given the ration would be:

Wheat, 5 pounds at $1\frac{1}{4}$ cents per pound	$6\frac{1}{4}$
Cut bone, 3 pounds at $1\frac{1}{2}$ cents per pound	$4\frac{1}{2}$
Grit and vegetables	$1\frac{1}{2}$
	$12\frac{1}{4}$

Making the total daily ration of one day to cost	$42\frac{3}{4}$ cts.
And when cut bone was fed	$41\frac{1}{4}$ "

As compared with the 41 cents daily ration of the previous year there is a slight increase $\frac{3}{4}$ cents in one case and $1\frac{1}{4}$ cents in the other. But the rations calculated at the price of wheat, of the previous year, one cent per pound and cut bone at 1 cent per pound, would show a decrease in the daily rations for the hens of 7 cents and about 3 cents in the case of the pullets.

THE QUANTITIES IN WHICH THE ABOVE RATIONS WERE FED.

The above rations were fed in the following quantities :—

CUT GREEN BONE in proportion of one pound to 15 or 16 hens.

MASH, composition of which is shown in previous page, about one pound to 15 or 20 hens. To the pullets a little every day.

WHEAT, 10 pounds at one time to 157 hens. To the pullets 5 pounds at one ration. When cut bone was fed only 2 pounds of wheat were given to the pullets.

The rations were fed at various times. For instance, cut bone would be given one day as a morning ration and the next in the afternoon.

The feeding of a small quantity of mash to the pullets every day was continued until the middle of January, when it was fed only three times per week, as the pullets were becoming too fat. It was thus shown that caution was required in pushing the pullets with an extra allowance of soft food. It is to be remembered that by this time the early pullets were well matured, as was to be seen in the increased size of their eggs as well as of their bodies. This was particularly noticeable in the case of the Barred Plymouth Rocks.

REASONS FOR ADOPTING THE ABOVE METHOD OF FEEDING.

The quantities given above may appear a small apportionment for 157 hens and 63 pullets, but (as shown later) vegetables and grit were always in liberal supply. The aim was not only to secure as great an output of eggs at as little cost as possible, but to secure the good health of the laying stock and immunity from vicious practices most frequently met with in the shape of egg eating and feather picking. The experience of past years has shown that active exercise is not only a chief factor in the winter production of eggs, but in the prevention of the two vices named. Experience has also taught that if the laying stock are overfed at the morning ration, as is too commonly the case, they are not inclined for exertion. Hence the object in feeding a light morning ration was to leave the layers ready to search for the small quantity of grain always scattered in the straw on the floor of the pens, soon after the ration was fed. The 5 pounds of oats as shown in Ration 1, for hens, were used for this purpose. The following summary of the manner and purpose of feeding may be useful as furnishing a daily Bill of Fare :—

1. The feeding of the morning ration in light quantity and as early as possible, so as to leave the layers inclined to search for more food.

2. About half an hour afterwards the scattering of a few hands-full of oats, or, other grain in the litter on the floor to incite the layers to exercise.

3. At 11 a.m. the feeding of lawn clippings which had been steeped in boiling water the night previous, for the purpose of supplying a cheap and wholesome form of green food.

4. No noon ration, except in the case of the pullets of late hatch, and which required gentle forcing.

5. About 3 p.m. the feeding of the afternoon ration in the shape of whole sound grain and in such quantity as to send the layers to roost with full crops. The grain was always thrown in the straw on the floor, so as to cause the hens to look for it.

6. The rations were fed as regularly as possible and careful observation made of their effect.

The lawn clippings, which usually came out of the hot water of good colour, were fed in the small narrow troughs fastened to the side of the pens, and were eaten with avidity. They had been gathered during the summer, thoroughly cured and put away. Where lawn clippings cannot be conveniently had, clover will make almost as good a substitute. Cut up into small lengths and steamed, clover is an excellent constituent of the morning mash and should always be in it.

Interior of part of Poultry House showing arrangement of Pens.

NO NOON RATION.

It will be noticed in the above bill of fare that no noon ration is given. It is not necessary in the case of the older hens and as, already remarked, should only be given to the pullets when their condition shows that it is required. If the layers wanted more food, than the quantity embraced in the rations, there were vegetables and roots in the shape of mangels or cabbage before them all the time and they could eat of them. Mica grit and ground oyster shells were always in abundant supply, as was pure water for drink. The vegetables, roots and grit were always eaten in such quantity as to show that they were indispensable. It is necessary to their well-being that the laying stock should eat a quantity of green food and grit and they are not likely to do so if overfed on mash or whole grain. It is imperative to have variety in the composition of and manner in feeding the rations. Experience goes to show that the cheaper foods, which are, as a rule, most abundant on a farm, make the most effective rations.

CERTAIN RULES EXPERIENCE HAS TAUGHT.

The experience of past years has, with other points already mentioned, made it very plain that the observance of certain rules is necessary before there can be an abundant supply of eggs in winter, immunity from vicious practices and the good health of the laying stock. These rules may have been mentioned in previous reports, but they are essential to success and will bear repetition. They are :—

1. Hens of proper age. Not over two years.
2. Varied, carefully prepared and regularly fed rations.
3. Grit, pure drink water and shell making material (in some form) in constant supply.
4. The keeping of the laying stock in as constant activity as possible.
5. A fairly comfortable house, with floor space of about 5 square feet to each layer.
6. The culling out of all non-layers.
7. Freedom of house and layers from lice.
8. Selection of laying stock from the best egg laying strains and of robust parentage. The latter applies with particular force to turkeys.

COMPARATIVE EGG YIELDS FOR THE PAST TWO YEARS.

The details which have been given, in a previous page, show wherein the rations differed in composition and quantity fed. The following tables will show the output of eggs for the years 1896-97 and 1897-98.

	1896–97.	1897–98.
November	568	267
December	1,466	1,469
January	1,540	1,653
February	1,351	1,553
March	1,668	2,063
April	2,139	2,430
May	1,846	1,837
June	1,190	1,115
July	859	389
August	736	325
September	655	428
October	339	300
	14,357	13,829

The above figures show a less number of eggs laid last year. It should be stated that in the season of 1896-97 there were 151 hens and 53 pullets as compared with 157

hens and 63 pullets last winter season, a difference of 6 hens and 10 pullets in favour of last winter. But by comparing the output of eggs during the winter months of the two years, it will be at once seen that a greater number of eggs were laid during the winter months of 1897-98 when eggs were of the most value for eating or setting.

	1896-97.	1897-98.
December	1,466	1,469
January	1,540	1,653
February	1,351	1,553
March	1,668	2,063
April	2,139	2,430
	8,164	9,168

The difference in the total number of eggs for the year may be accounted for by the number of broody hens during the summer months and likely to follow the extra laying of the late months of spring. It will be interesting to note if the lesser egg output of July, August, September and October is followed by a corresponding increase in eggs during the forthcoming winter months of December and January.

CARE AND TREATMENT OF PULLETS.

It is stated in a previous page that the pullets of last winter received a greater quantity of food than did those of the previous one. The determination to give the pullets more liberal rations was not dictated by the experience of the previous winter in the farm poultry department alone. But several correspondents had written to the effect that what were suitable quantities of food for the older hens did not seem enough for the pullets. In one case a correspondent had given the lesser quantities to growing pullets, which was certainly a mistake. While growing, the pullets require to be well fed and cared for and even after beginning to lay they may be gently pushed.

The composition of and quantity of rations fed to the pullets of last winter have already been given. The following will show the response made in the case of three pens of pullets, of late and comparatively early hatching, from beginning of winter laying in November until the breeding pens were broken up at the end of June following:—

Varieties.	November.	December.	January.	February.	March.	April.	May.	June.	Total.	Average
17 White Leghorn pullets	9	113	223	185	154	228	154	85	1,151	$67\frac{12}{17}$
28 B. P. Rock "	14	196	291	329	356	374	260	155	1,975	$70\frac{15}{28}$
10 S. L. Wyandotte pullets	...	8	69	84	98	114	74	42	489	$48\frac{9}{10}$
									3,615	

Among the above were comparatively early and late hatched pullets. Experience has made it clear that it is not advisable to have early and late hatched pullets together, particularly where the obtaining of eggs in winter is an object. Very often such a practice is attended with overcrowding. It is better to dispose of the late hatched pullets than overcrowd the older ones. To overcrowd is to seriously handicap the old pullets. Again, if the house is cold the late pullets most frequently remain non-progressive until spring. If too crowded, meanwhile, they are apt to pine away, and if they do not die, remain immature specimens. Where possible, hens and pullets should be kept apart.

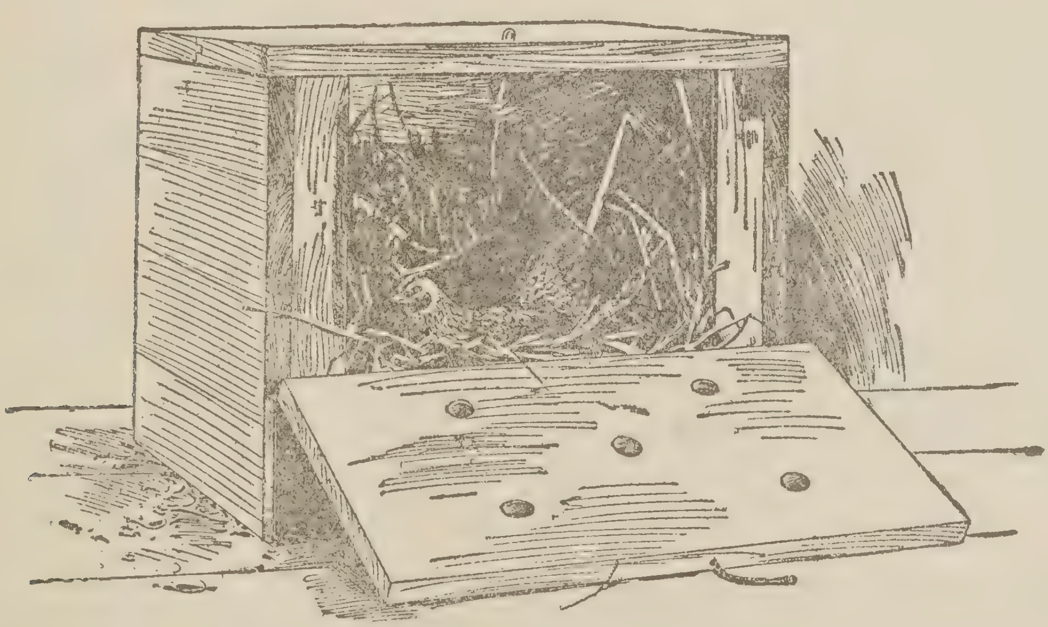
BREEDING PENS MADE UP.

At the end of February and the first week of March the breeding pens were made up as follows :—

Varieties.	Cocks.	Cockerels.	Hens.	Pullets.
Barred P. Rocks, No. 1 pen	1	....	9	....
" " 2 "	1	....	....	13
" " 3 "	1	....	....	12
White P. Rocks	1	....	9	....
Light Brahmas	....	1	9	....
Langshans	1	....	7	....
Coloured Dorkings	....	1	9	....
S. L. Wyandottes, No. 1 pen	1	....	8	....
" " 2 "	1	....	....	8
White Wyandottes	1	....	9	....
White Leghorns, No. 1 pen	....	1	11	....
" " 2 "	1	....	9	....
Brown Leghorns	....	1	2	....
Black Minorcas	1	....	9	....
White "	1	....	15	....
Andalusians	1	....	7	....
Crosses.				
White Indian Game-W. Java	....	1	6	....

On the 17th March the Light Brahma cockerel died suddenly, and soon after was followed by the Langshan cockerel. Both birds were valuable ones. They were replaced as quickly as possible and by equally good birds.

THE SITTING HENS.



Box Nest for setting hen

The sitting hens received no more attention than any careful farmer could have given them. The nests were made of straw arranged in small square boxes, without bottoms and with hinged door in front as shown in diagram.

Having no bottoms, the boxes could be placed on the ground or wooden floor, as desired. The nests were arranged, six or eight in number, in small compartments. Mixed grain, grit and drink water were in supply in each pen or compartment. On the nests being made they were liberally dusted with carbolic, or, other disinfecting powder. Two or three china eggs were then placed in each nest, and the broody hens, first being well dusted with a disinfectant, were placed on the eggs and shut in. Next morning the doors of the nest boxes, would be opened four at a time and the sitters allowed an opportunity to get out, if so inclined. If the newly set hens proved reliable the china eggs were taken away and the valuable eggs 11 or 13 in number—the former if early in the season—were given to them. Meanwhile the insect powder had likely killed any vermin that might have been on the body of the hens. Lice infested hens are not likely to sit at ease and when too much irritated have been known to leave their nests for good. Such precaution is necessary, particularly, where brooding hens are brought—as they often are—from not over clean quarters. Where incubators and brooders are used there is no likelihood of trouble from such a source.

	364 About 28 settings of 13. Average result 55 per cent.		193

Some of the small hatches, as shown above, were due to erratic sitters, or from eggs which were much shaken up in transit. As to the results from eggs from outside sources, experience varies. In some cases eggs from a great distance hatch well, while from eggs obtained from a near-by source there may be only two or three chickens. Much depends upon the freshness and fertility of the eggs before being sent, the manner in which the eggs are packed and the handling of the package *en route*. But the rest depends upon the manner in which the eggs are set and the care given to them by the receiver. It will be seen in the above table that 11 eggs from British Columbia

gave 7 chickens, while from 13 eggs from Rigaud, Que., only two chickens were hatched. No eggs could be more carefully packed than were the latter. The number of chicks hatched from the British Columbia eggs, and the vigorous growth made by them, told plainly of robust parent stock and strong germs. All that seems possible to be done under the circumstances, by the breeder, is to have his laying stock in proper condition, well mated, and to send out none but strictly fresh eggs packed carefully. It is for the express companies to transport as safely as possible, and for the consignee to set the eggs under a reliable sitter, as soon as possible after receiving them.

CARE AND SKILL REQUIRED IN OBTAINING EARLY FERTILE EGGS.

If the farmers' hens lay well during the winter months there may be difficulty in obtaining a satisfactory percentage of fertile eggs to put under the early March and April sitters, and from which are expected the early chickens, so desirable. Skill and experience are required in the feeding and handling of the laying stock, so as to have plenty of eggs at the period of high prices and early fertile eggs. Particularly so in cases where the layers are confined to limited quarters from the beginning to end of the winter months. Later on, when the season is warmer and the hens run out there can be no difficulty in having 10, 11 and 12 chicks from 13 eggs, usually put under a sitter, of medium size, at that period. But it is to be borne in mind that for market purposes and early layers, the early chicks are worth much more than those hatched in late May or early June. It should be the aim to have pullets to begin to lay in September and keep on doing so until the yearling and older hens are over their moult and join with them in egg production for the winter. It is worth some effort then to get the early chickens. Experience has shown that hens of the sitting varieties which lay well in winter make early sitters. It is an object then for the farmer, who desires early sitters and who does not use artificial means, to have his hens lay in winter.

FOOD AND GROWTH OF THE CHICKENS.

Experience of many years has proved the necessity of the careful looking after and proper feeding of the chickens from time of hatching. The chickens were allowed to remain in the nest with the mother hen twenty-four hours, or until they were quite strong on their legs. With the mother hen they were then placed in a coop on the grass outside, weather permitting. On the floor of the coop was dry sand to the depth of one or two inches. The coop was so arranged that the chicks could run in or out, while the hen was confined inside. By this method the chicks can be better looked after and more regularly fed. Their rations were placed on a clean board in front, which at night was used to securely fasten up the front part of the coop. The mother hen received her food in the shape of corn or wheat, and water was always within her reach. The first food of the chicks was stale bread crumbs, or stale bread soaked in milk and squeezed dry. Next day granulated oatmeal or rolled oats were added to the bill of fare. No foods have been found better for the newly hatched broods. Later on, crushed corn was added, and still later on whole wheat, in small quantities at first. As the chicks grew, a mash composed of shorts, cornmeal, bran, stale bread and a small quantity of blood meal was substituted for the more dainty and expensive first rations. For drink, milk sweet, or skimmed, sometimes mixed with water was used. The food was given, at first a little and often. Afterwards four or five times per diem. The sand in the coops was regularly renewed, and the latter were, occasionally, sprinkled with coal-oil, so as to prevent the lodgment of lice. Lice on hens or chickens was prevented, as far as possible, by occasionally rubbing the feathers of the former, under wings and breast the wrong way, with a cloth dampened, *not wet*, with coal-oil. Chicks showing signs of lice were dusted with insect powder. Experience has shown that chickens intended for early market, or for early layers, must be carefully looked after from time of hatching. It must be borne in mind that a chicken which has become "stunted" from being "stinted" in the first five weeks of its existence, will never make

a satisfactory fowl for any purpose. It is also to be remembered that chickens which are dragged about by an active mother in her energetic search for food for them, are more likely to develop muscle and sinew than flesh. And their future worth becomes hopeless, when after being left by the mother hen, they are allowed "to pick up their own living as best they can." On taking the mother hen with her brood from the nest it is well to give her food and water. She will then be more likely to brood her chicks quietly and contentedly.

WEIGHT DEVELOPMENT OF THE CHICKS.

With the foregoing food and treatment, but with no more care or attention than a farmer ought and could give his chickens, the following development was made :—

	Lbs.	Oz.
A white Plymouth Rock Cockerel hatched on the 18th April, weighed on 21st October, 6 months and 3 days after....................	7	4
The same bird on 22nd November, 1 month and 1 day later........	8	8
And on 6th December, 14 days later..............................	9	4½
Three other white P. Rocks hatched on the 25th April, weighed on 21st October following, 5 months and 26 days..............	5	14
" " "	5	12
" " "	5	12
A Barred P. Rock Cockerel hatched on 30th April, weighed on the 8th November following, 7 months and 8 days...............	8	6
Same bird on 6th December....................................	9	5
Another B. P. R. Cockerel hatched on same day weighed on 31st October, 6 months after..................................	7	5½
Three other cockerels of same breed hatched on 24th May, weighed on 31st October..	5	13½
" " "	5	6½
" " "	5	3

FOUR SILVER LACED WYANDOTTES.

Hatched 31st May, weighed 31st October..........................	5	5
" "	5	5
" "	4	13
" "	4	8

FOUR LIGHT BRAHMAS.

Hatched 9th May, weighed 31st October, 5 months, 22 days.......	6	12½
" "	6	8½
" "	5	13½
" "	5	7½

TWO INDIAN GAME—W. JAVA CROSSES.

The only cross made was with a White Indian game cock and White Java hens. Two of them made weight as follows :—

Hatched 16th May, weighed 31st October, 5 months 15 days.......	4	10½
" "	4	5½

This cross made finely shaped, plump market fowls, with well rounded breasts and meaty thighs. The flesh seemed white and fine in grain. When fattened, killed, plucked and dressed, but not drawn, the birds presented an unusually inviting appearance.

No. 1.

No. 4.

Front view of same cross.

THE MOULTING PERIOD.

During the moulting period the fowls received the necessary care and attention as fully described in report of 1896. Experience confirms the necessity of looking after the laying stock at this period of non-production, if eggs in November are desired. Any extra care and trouble at this season will be amply repaid by an output of eggs when they are of the highest value. The foods and treatment best calculated to secure an early moult and in the shortest time are subjects that are being earnestly discussed by the leading poultry breeders of Canada and the United States. Early hatched pullets to begin to lay when the older hens are moulting, and so keep up a continuous supply of new laid eggs are the real and most desirable solution of the problem, but they are not always easy to get (except by artificial means) in the colder districts of the Dominion. A farmer may have early setters from hens which have laid all winter and are of a setting breed, but he certainly will not have them from hens which only begin to lay in spring.

WHEN THE PULLETS COMMENCED TO LAY.

The pullets laid in the following order:—

Barred P. Rock pullet,	7th Nov.	Hatched	April.	
Black Minorca	"	5th Dec.	"	9th May.
Brown Leghorn	"	12th "	"	17th "
White Minorca	"	16th "	"	9th "
White P. Rock	"	17th "	"	25th April.

No effort was made to push the pullets, while running at large, beyond receiving regular feeding and good house accommodation. On going into winter quarters they were given rations calculated to stimulate egg production.

BEGINNING OF WINTER LAYING.

The hens went into winter quarters about the second week in November. Winter laying commenced about the first of December, somewhat later than last year.

DISEASES OF POULTRY.

Inquiries were made from time to time and from different parts of the country during the year, as to ailments affecting poultry. In most cases the sickness and fatal termination could be traced to roup in its varied forms. In several cases the symptoms described pointed to overfeeding and its consequence in liver derangement. As pointed out in a previous report the overfeeding of the morning mash and whole grain, with lack of green food, overcrowding, lack of exercise and over age are the most frequent causes of sickness and death.

ARTIFICIAL INCUBATION.

In the early part of the month of April last, a Prairie State Incubator of 100 egg capacity and a brooder were purchased from the Prairie State Manufacturing Company of Homer City, Penn., U.S.A. The incubator is heated by hot air which circulates over and around the eggs and is made hot by a coal oil lamp placed under and to the right side of the egg chamber. A sensitive thermostat over and partly under the egg tray regulates the temperature. Two shallow pans at top of egg chamber may be used for the supply of moisture, if necessary. The eggs are turned by fitting one tray on top of another, withdrawing them from the incubator and turning carefully. Full directions for its proper working accompanied the machine. The incubator was placed in a small office at the end of the main poultry building. The two first attempts to operate the incubator were not successful. In the first instance two chickens were hatched and only one in the second. The first two chickens hatched

in April turned out to be pullets and were early winter layers, one laying its first egg on 7th November, as already noted. On the 3rd of June, the incubator was again filled with 100 eggs of the following description :—

White Leghorns	36
Andalusian	22
Black Minorcas	18
Brown Leghorns	11
Colored Dorking	13
	100

The temperature of the room varied from 64 to 80.

The lowest reading of the thermometer in the egg chamber during the twenty-one days was $102\frac{1}{2}$ and the highest 103.

The eggs were tested twice, and thirty-five clear and doubtful ones removed, leaving 65 eggs with apparently strong and healthy germs.

On the 18th day one of the moisture pans was filled with warm water, the air space in the eggs showing necessity for moisture.

The result of the hatch was 25 chicks, five of which were not as strong as the others.

The eggs which did not hatch were carefully examined, and the great majority of them contained fully developed chicks which had apparently died between the 18th and 20th days. On being transferred to the brooder the chickens made satisfactory progress, with the exception of the weaklings which died at different times.

The results were certainly not very encouraging. But they go to show that further careful experimental trials will have to be made in order that the experience so essential to success can be gained. It would be unfair, if it were possible, to attribute with certainty the lack of better results to machine, or eggs, or operator until that experience is gained that will permit of expert decision. Future trials and careful observation will, no doubt, in time disclose where the shortcoming or fault is. Meanwhile, we know that the artificial hatching and rearing of chickens, ducks, &c., is the source of handsome profit to joint stock companies and private individuals in our own and other countries. The number of inquiries received from time to time as to machines and methods of operation shows that it is rapidly becoming more in vogue, and that a thorough knowledge of modern machines and methods is necessary in the interest of the great number of farmers who are now turning their attention to poultry breeding in all its different phases.

DUCKS AND GEESE.

From 16 duck eggs presented to the farm by Mr. A. Thompson, of Allan's Corners, Que., 7 Pekin and 1 Aylesbury duck were hatched. One Pekin duck died but the others made famous progress. One of the birds hatched on 26th June weighed on 20th October following, 3 months and 20 days, 8 pounds 3 ounces. Another hatched at same time weighed at same date, 7 pounds 1 ounce. The foregoing were drakes. An Aylesbury duck of same age weighed at same time 5 pounds 15 ounces. One wild goose remains, of the four sent 12 years ago to the farm.

EXPERIMENTAL FATTENING OF CHICKENS WITHOUT FORCED METHODS.

Of recent date much attention has been directed in Canada to the subject of fattening of chickens—and so improving their condition—by the English and French methods of "cramming," or forcing of food into the crops of the birds by a machine operated in most cases by foot and in many places by hand, and known as a cramming machine. According to this method the fowls or chickens are penned in specially arranged coops, and allowed to eat all they will or can for ten or twelve days, of a ration composed in England, principally of finely ground oats, skim milk and tallow. At the end of the time mentioned experience has shown that the birds do not eat with the same avidity, as they did at first and the crammer is then brought into requisition. The time taken to properly fatten a bird is 21 days, in some cases a week longer. The chickens which are of mixed breeds and of both sexes, are purchased from the English farmers, when three to five months of age by the higglers or fatteners, who place the birds in long rows of coops and in numbers varying from 320 to 1,200, according to size of premises. The rearing of the chickens is the work of the farmer. The fattening is done by the higgler. They are, in the great majority of cases, two distinct occupations and are a source of profit to both first and second parties. It is an object to obtain large chickens which will make heavy weight. Crosses in which Indian Game or Dorking predominate are preferred. But will it pay our farmers to breed crosses, solely for flesh production, while they have within easy reach thoroughbreds which not only make greater and more rapid flesh development, but good winter layers? Our farmers have a winter market of paying prices. With thoroughbred Plymouth Rocks, Wyandottes, &c., they are in a position to cater to the winter market and rear heavy weight chickens in season, for export or home markets. They have actually two strings to their bow. Experience has shown that the barn-yard fowls, or "scrubs," to be found in such numbers on the farms of the country, are neither good for eggs nor flesh production. First crosses of the larger thoroughbreds are certainly better flesh formers, but they must be made every year, or they will degenerate. All things taken into consideration there is every reason for our farmers stocking their barn-yards with those thoroughbreds which Experimental

Farm reports for some years past and the writer on many platforms, in different parts of the country, have named as the best winter layers and the heaviest and most rapid flesh formers. In connection with the foregoing, the following experiment, which was carried out with the view of finding out the relative merits, as flesh formers, of scrubs, first crosses and thoroughbreds, will be of interest. The experiment was commenced on the 1st of November, and continued for five weeks. Special coops with slatted bottoms and fronts and with feeding troughs in front, were erected in an upper compartment of the main poultry building.

The coops were filled with 34 cockerels and 2 pullets of the following description:

8 barn-yard chickens, some showing Barred Plymouth Rock and Wyandotte origin and others Leghorn and Minorca, were purchased from neighbouring farmers.

4 cockerels of first cross between Light Brahma and Buff Cochin. They were purchased from a farmer on the Richmond Road.

4 first crosses of White Indian Game and White Java hens from Experimental Farm poultry department. Two of the number were pullets.

20 thoroughbred cockerels of the following breeds, viz.:

4 Barred Plymouth Rocks, 4 Light Brahmas, 4 Silver-laced Wyandottes, 4 White Plymouth Rocks, 4 White Wyandottes. All from the Experimental Farm.

These were divided in groups of 4 each and the birds were respectively numbered from 1 to 36.

The rations were composed of—

2 parts of finely ground oatmeal,
1 " " barley meal,
1 " ordinarily ground cornmeal,

and were mixed with sweet milk.

The birds were fed at 7 a.m., noon, and 3.30 p.m., each day, with regularity, all the food they could eat. The exact figures of amount fed are given elsewhere.

On the 15th November, 15 days from beginning of experiment, beef suet in the proportion of one ounce to each group of 4 fowls was added to the ground grains ration and fed three times per day.

Water was regularly supplied, as the birds seemed to desire it.

Mica crystal grit was furnished twice during the five weeks.

The birds were weighed on the afternoon of 31st October, placed in their coops and fed their first ration, a light one. The regular feeding of the rations began next morning, 1st November. The nature and progress of the experiment are shown in the following tables.

The first table shows the weight of the birds on 31st October, their progress per week, the gain made by each bird per week, and the total gain at the end of five weeks. The last column shows the loss in weight from end of fifth week, December 6th to December 8th, two days. The birds were then fasted for 36 hours and killed. It should be explained that the original intention was to dispose of the birds at the end of the fifth week, but as circumstances did not permit they were fed for two days longer.

It is to be borne in mind that the birds were allowed to partake of the food in as great quantity as they felt inclined. There was no machine used for the purpose of forced feeding.

TABLE I.

SHOWING weight of birds on 31st October, when put into coops to fatten; the progress made by each bird per week, and total gain made in five weeks by each bird. The last column shows the weights and losses at end of the two extra days.

On the 17th November, No. 13 Light Brahma Cockerel died. On being examined the liver was found deep in colour and highly gorged with blood. There was an accumulation of 3 ounces of fat around the gizzard. The organs and body were otherwise healthy. There was no apparent cause of death.

Nos. 20 S. L. Wyandotte and 34 White Wyandotte were not in good condition for a portion of the time. They did not eat well and lost in weight.

TABLE II.

THE following table shows the gain in weight and quantity of food consumed by the nine groups during five weeks and two days. The last two days show a loss in weight which indicates that after a certain time there is little or no progress by their eating at will :—

——	Gain 1st week.		Food Consumed.		Gain 2nd week.		Food Consumed.		Gain 3rd week.		Food Consumed.		Gain 4th week.		Food Consumed.		Gain 5th week.		Food Consumed.		Last 2 days.		Food Consumed.

RESULTS AFTER THE FASTING, KILLING, PLUCKING AND COOKING.

As already stated, the birds were fed their last ration on the afternoon of December 7th. They were given no food for 36 hours previous to being killed, in order to secure complete emptiness of crops and intestines. This is a matter of great import. If crops or intestines contain any food after death it is likely to decompose and ruin the carcass. It is an imperative condition, in the preparing of poultry for shipment to Great Britain, that the birds be fasted for 24 to 36 hours previous to killing. Experience has shown that 36 hours is the better margin. The birds were killed by dislocation of the neck. The easiest manner of killing and causing instantaneous death. The birds were immediately plucked. The plucking of the bird can be much more expeditiously and perfectly done while the body of the fowl is warm. The birds were carefully dry picked. Care was taken to avoid any abrasions of the skin, which is apt to occur with careless handling. The scalding of the birds, in order to permit of easy picking, should be avoided in any case, but it ruins the birds for sale in the English market. After plucking, the birds were placed in a small trough made by nailing a board to the wall of the loft of the poultry house at an angle of 45 degrees. The birds were allowed to remain in this trough until cool. Meanwhile they had assumed a round and compact shape, which added much to their appearance. The birds were then packed into cases to be sent to cold storage, with the exception of 9 which were retained for further

experiment. The birds chosen were composed of one from each group and were fairly representative ones, but by no means the best. The following table shows the loss in weight occasioned by 36 hours fasting, plucking and the waste in dressing and boiling:—

TABLE IV.

SHOWING loss in weight from fasting, plucking, dressing and boiling.

EXPERIMENTAL FARM FOR THE MARITIME PROVINCES

REPORT OF R. ROBERTSON, SUPERINTENDENT.

NAPPAN, N.S., 30th November, 1898.

To DR. WM. SAUNDERS,
Director Dominion Experimental Farms,
Ottawa.

SIR,—I have the honour to submit herewith the following report of the operations on the Experimental Farm for the Maritime Provinces, at Nappan, N.S., during the year 1898.

WEATHER.

December, 1897, came in cold with severe frost on the 3rd, followed by open weather to the 17th, when it set in cold again, remaining so until the 27th, which was moderate. The mercury fell to 2° below zero on the 30th. The first of January was more moderate, but the temperature fell to 4° below zero on the 3rd; and 3, 10 and 3 degrees below zero on the 4th, 5th and 6th respectively. The 7th and 8th was again soft weather, the mercury falling and keeping from 2° to 10° above zero as a minimum temperature until the 18th; when the thermometer registered 23° below zero; on the 19th, 22°; on the 22nd, 8°; on the 23rd, 7°; on the 26th, 5°; on the 27th, 0°; on the 28th, 8°; on the 29th, 23°; on the 30th, 24°; and the temperature fell to 30 degrees below zero on the 31st.

Slight snow fell on the 3rd of January and sleighs were used in some places; but sleighing was not good until the 13th, when there was quite a fall of snow, and on the 21st we had a heavy storm with wind, followed by a more severe one on the 24th. The first of February was still cold with a snow storm on the 1st and a very heavy one again on the 3rd. On the 4th of February, the mercury registered 17° below zero, but did not fall to zero again after that time. The weather was milder on the 6th and continued so until the 12th. The remainder of the month was pleasant with some quite severe frosts.

March was quite a moderate month being somewhat broken with snow and wind storms until the middle of the month. On the 30th there was a heavy rain; with a strong wind and another rain storm on the 31st and snow and rain again on April 1st. April was fine after this until the 15th and 16th, which days were wet; then it was again fine until the 21st, on the 25th it rained and on the 26th it snowed all day, but rained again on the 27th, the weather remaining cloudy and dull until May the 3rd, after this fine weather prevailed until the 14th, when there was a heavy warm rain. No heavy rain occurred again until the last of May and first of June.

On the 13th of April, the first grain was sown on a dry part of the farm, on the 23rd a small plot of barley was sown, but no further seed was sown until the 5th of May. Seeding then continued uninterrupted from the 9th to the 14th and from the 21st to 29th. The month of June was somewhat colder than usual being only fair growing weather and having little rain until the latter part of the month. July came in fine and warm and good growing weather continued.

The first hay was cut 1st July, and two weeks of excellent haying weather followed, after which the season was broken. The last of the English hay was gathered by 10th

August, and on the 30th broad leaf haying was finished. Winter Rye was cut 2nd August, and the first spring sown grain was cut 6th August. After the middle of August there was a week of splendid weather, with broken weather again until September.

The first frost occurred on the 13th September, it did not, however, fall below 31°, yet this injured some of the grain plots.

September was an exceptionally fine month until the 23rd, when it became wet and continued dark with almost continuous rains, not often heavy, until the 25th of November, when the first severe frost occurred. On the 11th of November there was a slight fall of snow, followed with rain, and a very heavy wind and snow storm on the 27th, the remainder of the month continued wet.

The fall has been exceptionally open having no heavy frosts. The thermometer registered the lowest temperature for September, 31° on the 22nd and 26° on the 25th; for October 26° on the 7th; 28° on the 10th; 24° on the 11th; 32° on 14th and 24° on the 29th; for November 31° on the 2nd; 28° on the 4th; 29° on the 8th and 31° on the 10th.

Maximum and minimum thermometer readings for the year beginning with 1st December, 1897, and ending with 30th November, 1898.

HAY.

The hay crop on the marsh was a good average yield, while the upland was over an average crop. The 35 acres of marsh, growing English hay, produced 81 tons 1,000 pounds and the 6 acres of broad leaf marsh 10 tons 400 pounds. Thirteen acres of upland yielded 38 tons 1,600 pounds making total of 130½ tons. Considerable rain during hay making time made the haying season long; the hay was, however, gathered in good condition.

EXPERIMENTS WITH OATS.

The land on which the oat plots were sown was a light clay loam. It was mudded in the winter with 60 two-horse loads of marsh mud per acre. Complete fertilizer at the rate of one barrel per acre was drilled in with the seed. This land was previously devoted principally to grain crops and was very poor and weedy, never having had any barn-yard manure. Mammoth Red Clover, 10 lbs. per acre was sown with the grain, but made only poor growth.

Sixty-four varieties were sown in one-twentieth acre plots on the 11th and 12th of May. There was some smut in the grain, the varieties named King and Dawson suffering more than the others. Most of the grain was slightly rusted. The following results were obtained :—

NOTE.—The weights given here, and also in all other grain tables in this report, were taken as the grain came from the threshing mill, and are not the maximum weights that the grain could be brought to by cleaning.

TREATING OATS TO PREVENT SMUT.

In order to test the relative value of different materials for treating seed oats to prevent smut, experiments were tried in accordance with instructions received from the Director, with three different kinds of oats, which were tested as follows:

1st. Bordeaux mixture made with 4 lbs. of sulphate of copper to 4 lbs. of lime, in a 40 gallon barrel full of water in which the seed was soaked for four hours.

2nd. Formalin 2 parts in one thousand made by mixing 3 oz. of formalin in 10 imperial gallons of water in which the seed was soaked for two hours.

3rd. Formalin 3 parts in one thousand made by mixing 4½ oz. of formalin in 10 imperial gallons of water in which the seed was soaked for two hours.

After the grain had been soaked for the periods named it was taken out of the solution, where it had been suspended in a bag, and drained for a short time after which it was exposed to the air and dried before sowing. A fourth plot of each variety was not treated but left as a check plot. The seed was sown in plots measuring 33 by 3 feet on 13th May, and a record of the smutty heads and those free from smut was taken 20th August. The following results were obtained.

EXPERIMENTS WITH BARLEY.

The test plots of barley consisted of 24 varieties of six-rowed and 17 varieties of two-rowed. The soil on which they were grown was a clay loam which had roots as a previous crop. One barrel of complete fertilizer was used per acre. The fertilizer was drilled in with the seed. The "Wisner" seed drill with fertilizer attachment was used for sowing all grain plots.

Some of the varieties had smut in them; but the straw was free from rust. Ten pounds of clover, the Mammoth Red variety per acre was sown with the grain and made a splendid growth; having quite a sward to turn down late in the autumn. The seed was sown 10th May in one-fortieth acre plots at the rate of two bushels per acre. The results obtained are given in the following table:—

EXPERIMENTS WITH SPRING WHEAT.

Forty-two varieties of spring wheat were sown in these experimental plots. The straw rusted very badly and consequently the grain did not fill out, the crop being almost a complete failure in some cases. The soil on which these wheats were grown, was a clay loam, similar to that on which the barleys were grown and received the same treatment.

The plots were one-fortieth acre each. The seed was sown 9th May at the rate of 1¾ bushels per acre. Mammoth red clover at the rate of 10 pounds per acre was sown at the same time with the grain. The clover made vigorous growth and quite a heavy crop was consequently turned under when ploughed in the autumn. The results obtained were as given below:—

EXPERIMENTS WITH PEASE.

Forty-seven varieties of pease were sown on land similar to that on which the oats were grown. No mud was applied, but complete fertilizer at the rate of one barrel per acre was used. This land was very poor, never having had any barn-yard manure. Soon after the plots were sown, a weed called "spurry" *Spergula arvensis L.* came up so thickly that it completely choked the growth of the pease so that it was thought advisable to cut many of them for green fodder. Under the circumstances no comparative report can be given which would be of any value as to the relative merits of the varieties tested.

RESULTS OF EARLY MEDIUM AND LATE SOWINGS.

The sowing of grain at different periods to test the relative value of early, medium, and late sowings was again carried on this year. The first set of these plots was sown 5th May and continued until 9th June, one set each week, making six sowings in all, one week apart. Two varieties each of wheat, barley, oats and pease were used in this test.

The soil was a clay loam of poor quality. Pease had been grown on the land for the two previous years. This season it was worked up with the disc harrow and stable manure at the rate of twenty 30 bushel cart loads per acre was applied and worked in. The seed was then sown, and one barrel of complete fertilizer per acre was applied at the same time. The last set of wheat plots were injured by frost on 13th September. The early wheat plots were more rusted than the later ones. The oats were slightly rusted and the barley had a considerable quantity of smut in it. The plots were one-fortieth of an acre each. The results obtained were as follows:—

OATS—RESULTS OF EARLY, MEDIUM AND LATE SOWINGS.

*Destroyed by frost.

EXPERIMENTS WITH INDIAN CORN.

The previous crop grown on this land was hay. Stable manure at the rate of 20 30-bushel cart loads per acre was spread on the sod and ploughed under. The land was worked up and marked out in rows and hills 3 feet apart. Three barrels of ashes and 300 pounds of complete fertilizer per acre was sown as the seed was planted and covered in at the same time.

One set of plots was planted in rows 3 feet apart and a duplicate set alongside in hills 3 feet apart each way. The soil was a light clay loam. Twenty-five varieties were planted on June 1st and the following crops was obtained :—

CORN PLANTED AT DIFFERENT DISTANCES APART.

Three varieties of corn were used in this experiment, and three sets of rows were sown for each plot with duplicate plots in hills. The crop from the middle row of each plot was weighed and the yield per acre ascertained from it; by so doing the narrower or wider rows alongside would not influence the weight of the row cut.

These were grown on land similar to that on which the corn was grown for test of varieties and the same preparation was given. The plots were planted 1st June and cut 26th September. The wider rows gave a larger proportion of ears. The results obtained from this experiment are given below in yields per acre:—

INDIAN CORN GROWN AT DIFFERENT DISTANCES APART.

Varieties and how sown.	Rows.		Hills.	
Longfellow.	Tons.	Lbs.	Tons.	Lbs.
2 feet apart	18	1,950	17	1,475
2½ "	17	980	15	360

EXPERIMENTS WITH FERTILIZERS ON INDIAN CORN.

The land on which these experiments were conducted had previously grown hay and clover. The soil was a light clay loam, and the manure was spread on the sod and then ploughed under. The land was ploughed just before planting, was then worked up, and after the corn was planted the complete fertilizer was sown broadcast and harrowed in.

Plot 1.—Twenty 30-bushel cart loads of stable manure per acre and 250 lbs. of complete fertilizer were used per acre. The yield was 13½ tons per acre.

Plot 2.—250 lbs. of complete fertilizer was used per acre. The yield was 8 tons per acre.

Plot 3.—Had no fertilizer and no manure. The yield was 7 tons 1600 lbs. per acre.

It will be observed that the effect of the complete fertilizer on the weight of the corn crop was very slight. The field on which these tests were made was one-half acre, and the three plots referred to were $\frac{1}{20}$th acre each, and were measured off from the half acre.

EXPERIMENTS WITH TURNIPS.

The soil on which these were grown was of a clayey loam nature. The previous crop was corn. The land was ploughed in the spring and manured with twenty-five 30-bushel cart loads of stable manure per acre, after which it was again ploughed and worked up. Fertilizers at the rate of 250 lbs. of complete fertilizer per acre, 200 lbs. of bone meal and 200 lbs. of salt per acre were then sown broadcast and harrowed in, after which the drills were run up 28 inches apart.

Two sets of plots were sown, two weeks intervening between the sowings. The yield of all the root plots per acre has been calculated from the quantity obtained from two rows each 66 feet long. Nineteen varieties were sown, which gave the following results :—

TURNIPS.—TEST OF VARIETIES.

EXPERIMENTS WITH POTATOES.

One hundred and two varieties of potatoes were planted all on the 4th of June on a light clay loam. The previous crop grown on this land was barley and the land had a good catch of clover on it which was ploughed under in the spring. This was then worked up and drills were run 30 inches apart. 400 pounds of "Pidgeon's" potato fertilizer was sown per acre in the drills and the seed planted. No barn-yard manure was used. The potatoes were sprayed with Bordeaux Mixture 27th July, 5th August and 11th August. Paris green was also used in the first two applications. The plots consisted of two rows each 66 feet long, and 30 inches apart. All the varieties were dug on the 22nd September, and the following yields were obtained.

Many of the varieties were injured more or less by rot. Among those which suffered most from this cause were the following—Lizzie's Pride, Maggie Murphy, Early Gem, American Giant, Honeoye Rose, Charles Downing, Pride of the Market, Carman No. 1, Columbus and Brownell's Winner.

EXPERIMENTS WITH JAPANESE MILLET.

The land on which this millet was grown was previously in timothy and clover. The soil was a clay loam, and no fertilizer was applied. The seed of this millet from Japan was forwarded by the Director with instructions for conducting these experiments. The object was to gain information as to the best distance at which to sow this variety of millet to produce the largest returns. The seed was sown 5th June, and the crop harvested and weighed 13th September. The following table gives the yields obtained per acre.

How sown.	Yield per acre. Tons.	Lbs.
1, Sown broadcast	14	1,870
2, Sown in drills 15 inches apart	16	1,960
3, " 12 "	12	205
4, " 9 "	13	780

EXPERIMENTS WITH HORSE BEANS.

These experiments with horse beans, sown at different distances apart, were carried on in accordance with instructions from Ottawa, for the purpose of gaining information as to the quantity which could be grown upon an acre under different methods of planting, also to compare their value with soja beans grown under similar treatment. The soil on which these plots were grown was a clay loam in a fair state of fertility—complete fertilizer only at the rate of 400 pounds per acre was sown in the rows when the seed was planted. The plots were one-fortieth acre each. They were sown 5th June, and the crop was harvested 26th September. The following results were obtained :—

How Sown.	Yield per acre. Tons.	Lbs.
1, Sown in drills 2 feet apart	13	400
2, " 2½ "	11	1,400
3, " 3 "	9	....

EXPERIMENTS WITH SOJA BEANS.

The seed used in these experiments was of a very early variety of soja bean from Japan, sent by the Director. The experiments were planned with the object of finding out the best distance apart for growing this variety of bean, and also its value as a forage crop. They were grown in plots of one-fortieth acre each; these plots were adjoining those on which the horse beans were planted, and received similar treatment. The seed was sown 5th June, and the crop was cut and the following particulars obtained 26th September:—

How sown.	Yield per acre. Tons.	Lbs.
1, Sown in drills 2 feet apart	5	600
2, " $2\frac{1}{2}$ "	4	600
3, " 3 "	$3\frac{1}{2}$	...

FIELD CROPS OF ROOTS.

MANGELS.

The land used for this crop was in roots the year previous. It was ploughed in the spring and manured with twenty 30-bushel cart-loads of stable manure per acre, then ploughed again and worked up. 250 pounds of complete fertilizer, 200 pounds of bone-meal and 200 pounds of common salt were sown broadcast per acre. The rows were then drilled to twenty-eight inches apart. The seed of the varieties named was sown 28th May, and the yields were as follows:—

Name.	Yield per acre. Bush.	Lbs.
Yellow Globe	1,053	..
Giant Yellow Intermediate	971	20
Mammoth Long Red	955	16

TURNIPS.

The land for this crop was similar to that on which the mangels were grown. One-half of it, however, was in a barley crop the previous season. The same quantity of barn-yard manure was used and the land had the same treatment as the mangels, but in place of the additional fertilizers given to the mangels, Bowker's square brand fertilizer at the rate of 400 lbs. per acre was applied on one-half, and the Thomas' Phosphate at the rate of 400 lbs. per acre was applied to the remainder. The field of $1\frac{1}{3}$ acres yeilded 1,275 bushels. In this case there was a slight increase of yield of 750 lbs. only where the Bowkers fertilizer was used.

FIELD CARROTS.

These were grown on land adjoining the mangel plots and received the same kind of treatment. The following varieties were sown 28th May in two rows each 528 feet long:

Name.	Yield per Acre.			
Mammoth Intermediate	651 bush.	4	lbs.
Giant White Vosges	628 "	16	"
Half-long White	618 "	8	"
White Belgian	532 "	..	"
Short White Vosges	435 "	44	"
Orange Giant	397 "	44	"

GENERAL STATEMENT OF CROPS.

Five acres of marsh yielded 125 bushels of oats. The upland, in grain of different sorts, not including the plots and including 50 bushels of buckwheat, yielded 475 bushels, making a total of 600 bushels of grain.

The total root crop was 3,329½ bushels made up as follows: Turninps, 1,504 bush.; mangels, 1,517 bush.; carrots 257 bush. 44 lbs.; sugar beets, 50 bush. 49 lbs.

All the corn, except the uniform test plots of varieties and the plots sown at different widths, were sown with horse-beans, at the rate of one peck of horse-beans per acre with the usual quantity of corn. These were cut and weighed together and have been reckoned in this general estimate as corn crop. The horse-beans formed but a small percentage of the whole. About six acres in all were covered with this mixture. The sunflower heads amounted to 2 tons 215 lbs. The total amount of ensilage secured was 66 tons 905 lbs.

STOCK.—CATTLE.

In addition to the dairy stock that was on the farm, when I assumed the superintendency, fifteen grade cows and six thoroughbred cattle have been purchased. The stock now consists of :—

Two Guernsey cows, one Guernsey bull, two Guernsey bull calves; two Ayrshire cows, one bull (1 year old), two Ayrshire heifers; two Holstein cows, one Holstein bull calf, one Holstein heifer calf; twenty-five Grade cows.

Sixteen 2 and 3 year old steers, representing the Hereford, Polled Angus, and Shorthorn breeds were lately purchased. These, together with four scrub cattle, also lately purchased, are included in a feeding test which will be carried on this winter.

PIGS.

The thoroughbred stock of pigs kept are 3 Tamworths, 2 Yorkshires, and 2 Berkshires, with from 25 to 40 grades and crosses, which are disposed of from time to time, as pork, weighing from 140 to 180 pounds per carcase.

The value of the feed fed to the grade pigs during the year has been kept on record, with the object of finding out the value of the skim milk fed, with the result that, from 15 to 17 cents per hundred was obtained from it by converting it into pork. Experiments are now being conducted with different lots of pigs to determine the value of different grain feeds as well as that of skim milk for the production of pork.

SHEEP.

In the spring 24 sheep were purchased and put upon a very poor piece of land containing 10 acres. The object in so doing was to raise the fertility of that piece of land by the sheep alone without the additional use of commercial fertilizers or stable manure. Two acres of this field was fenced off and sown to rape for feeding later in the season; but the land was so poor that the crop grew only 3 inches high, and did not furnish much food. While the land may have been improved, the sheep did not do at all well; another season may give better results. There are at present on hand 25 old sheep and 4 lambs. The value of the remainder of the increase, and the wool, was given to the sheep in feed while on the pasture.

POULTRY.

The different breeds of poultry kept are :—

White Leghorns, of which there are in all.	20
Black Minorcas.	14
Plymouth Rocks.	9
White Wyandottes.	2
Pekin Ducks.	4

View on the Experimental Farm at Nappan, Nova Scotia, showing part of the Experimental Plots.

View on the Experimental Farm at Nappan, Nova Scotia, showing Farm Buildings and Group of Cattle.

No account has been kept of the number of eggs laid by the different breeds; that, however, will be attended to in future.

HORSES.

There are at present on the farm seven horses. During the past year three horses have been purchased to replace three of the oldest ones which were disposed of.

BEES.

Three colonies of bees were received from the Central Experimental Farm on the 1st of May last. These were immediately opened and appeared to be in good condition, but in the course of two weeks one of the hives was deserted, leaving two, which yielded 55 pounds of honey, in one pound sections, and two additional hives. These were put in the cellar of the superintendent's house 1st December, and weighed 58, 52½, 38 and and 36½ pounds respectively.

They were placed for winter in a part of the cellar furthest from the door, which now registers a temperature of 40 degrees. This place was partitioned off with matched lumber for the purpose of shutting out the light and also the heat from the furnace. The hives were placed on a shelf, 2 feet from the ground, which was resting on two boxes. The tops of the hives were covered with a cushion 4 inches thick made of chaff, and the sides were unprotected, the openings being left in the front of the hives.

IMPROVEMENTS.

Three new buildings were erected this fall, namely: Summer kitchen and wood-shed on the horticulturist's house, an extension of 34 feet to the pig house, and an ice house with refrigerator room. In the south-east corner of the main barn, directly over the cow-stable, a hen house has been fitted up. This is kept warm by the animal heat from the stable below, which is allowed to come in through openings in the floor. The stable below registers from 50° to 60°, and it is expected that the temperature of this room will not fall below freezing. A small room was also fitted up in one corner of the cellar of the superintendent's house for bees.

WATER SUPPLY.

The water supply up to this season has been very defective, but during the summer a spring was found in the wood about ¾ of a mile from the buildings, and this water has since been brought in galvanized iron pipes and put in all the buildings of the farm.

The water supply now shows every indication of being ample, and is apparently the finest of water. A sample of it has been sent to the chemist of the Experimental Farms, Ottawa, for analysis who has reported on this water as follows:

"On the 24th December, 1898, we received a sample of water taken from the new water supply at the Experimental Farm, Nappan, N.S. It was submitted to a careful examination, with the following result:—

	Parts per million.
Free Ammonia	·016
Albuminoid Ammonia	·086
Nitrogen as Nitrates and Nitrites	·094
Chlorine	4·8
Total Solids, at 100° C	58·4
Solids, after ignition	38·4
Loss on ignition	20·0
Phosphates	very slight traces.

"The water, as received, was perfectly clear, brilliant and odourless. It possessed a faint yellow tint when viewed in the 2-foot tube, due to slight traces of dissolved peaty matter.

"The analytical data show it to be an exceedingly good water, exceptionally pure, and one eminently suited to drinking and household purposes.

"FRANK T. SHUTT,
"*Chemist, Experimental Farms.*"

UNDERDRAINING.

The balance of the wood orchard was tile drained last fall, and since that a few drains were laid where greatly needed. It is hoped that more underdraining will be done next year, as the benefit of the draining done in the past is very apparent.

VISITORS.

A great number of people visited the farm during the year, especially in the summer months. There were five picnic parties to the farm during the summer. The largest being from Pictou County, N.S., on 7th July. From conversation with leading farmers in Prince Edward Island and New Brunswick, I have every reason to expect large excursion parties from each province another year.

CORRESPONDENCE.

Besides the distribution of reports and circulars, 1,573 letters were received and 1,384 were sent out.

DISTRIBUTION OF SEED GRAIN AND POTATOES.

In all 533 applicants have been supplied during the past year with 3 pounds samples of potatoes, oats, wheat, barley, pease, buckwheat and rye.

The number of packages sent out are as follows:

Potatoes	385
Oats	232
Wheat	137
Barley	122
Pease	93
Buckwheat	13
Rye	4
Total	986

EXPERIMENTS WITH MILCH COWS.

With a view to demonstrate whether a fairly good herd of dairy cows, getting credit for their products at current prices, and being charged for their feed at market rates, would leave a balance on the debit or credit side, an experiment was begun with all the cows in the herd at Nappan, on 28th November, 1897, and continued until 27th November, 1898.

As the prices of product and feed change so much for summer and winter, the experiment was divided into 26 weeks for winter, and the same for summer; and the prices of their product and feed averaged for each period. The cows were charged with all the feed they consumed. The bran, and most of the meal fed was bought and charged at the prices paid. The roots were valued at 5 cents per bushel, corn ensilage at 5 cents per bushel and hay at $6.00 per ton.

The feed was changed from time to time, the average cost of daily ration during the winter months, while in full milk, was 16 cents per day and $2.55 per month while dry. One of the different rations, while in full milk, was, corn ensilage 30 pounds at $2\frac{1}{2}$ cents, roots 30 pounds $2\frac{1}{2}$ cents, hay 12 pounds, $3\frac{3}{5}$ cents, chop (mixed grain) 4 pounds 4 cents, bran 3 pounds $2\frac{1}{4}$ cents, cotton seed meal $\frac{1}{2}$ pound $\frac{3}{4}$ cents—$15\frac{3}{5}$ cents. Another was corn ensilage 40 pounds, hay 20 pounds, chop 4 pounds, bran 3 pounds, cotton seed meal 1 pound—$16\frac{3}{4}$ cents.

Different quantities were fed to different cows, according to their ability to consume and produce, which was charged accordingly. Twelve were in full milk when the experiment was begun, the others coming in fresh at various times until spring.

The summer feed consisted of a rather poor pasture field, supplemented with $\frac{1}{4}$ acre green clover, 3 acres of vetches, oats and pease (grown together), 1 acre clover after grass and $\frac{1}{4}$ acre green corn, for which the cows were charged $1.50 per month while milking and $1 per month while dry. Some meal was fed in November to the cows fresh in milk, which was also charged.

They were kept in the stable from 28th November, 1897 to 1st June, 1898, with only an occasional fine day out in the yard. They were fed twice only, each day, and had water before them all the time, with the stable kept as near 60° Fahrenheit as possible. They were fed, cared for, and milked by the same person as regularly as possible.

From the 1st of June to 1st July, they were out night and day, during July, August and part of September they were out at nights and kept in during the day, the remainder of September and to 1st November they were out during the day and in at nights. After 1st November they were in all the time, except on occasional fine days, and were charged the same as in the winter months, making seven months winter feeding, and five summer feeding during the year. No charge was made for labour, the manure being put against that.

A careful record was kept of each cow's milk by weighing each milking as milked.

A sample of each cow's milk was taken twice each week, and the percentage of butter fat in it determined by the Babcock test, which test was carried on under the supervision of J. E. Hopkins, superintendent of the Nappan Creamery. The weight of butter was determined on the basis of 84 pounds of butter fat making 100 pounds of marketable butter.

The milk was sent to the creamery, and the cows credited with the weight of butter produced, at the price paid to all patrons of the creamery, which averaged for the six winter months $20\frac{1}{7}$ cents, and 18 cents for the summer, less $4\frac{1}{2}$ cents per pound charged by the creamery for making butter and hauling milk. The skim milk was fed to pigs and calves, and credited to the cows at the rate of $12\frac{1}{2}$ cents per hundred pounds of skim milk.

The following table will show the results obtained. The figures are arranged in each case in two groups, one for each half year. Nos. 3, 4 and 27 were sent to the butcher at the end of the first six months.

* Winter. † Summer. Number 16 had been milking 210 days before entering test. Numbers 3, 4 and 27 sold to butcher at end of first half of test.

One striking fact is that cows of equal quality (as near as can be judged) which were fresh in the fall gave more profit than their equals fresh in the spring, besides consuming more of the rough products of the farm. For instance, Nos. 21, 24 and 26 were fresh in the spring, and consumed $117.62 worth of feed, paid for it and left a balance of $63.13 to their credit. While Nos. 6, 17, 22 and 25 that were fresh in the fall consumed $154.51, paid for it and left a balance of $106.11, being $10.75 per cow in favour of the fall calved cow.

EXHIBITIONS ATTENDED.

An exhibit of the farm produce was made at St. John, N.B., from 13th September to 20th, and at Halifax, N.S., from 22nd September to the 29th. I also attended the exhibitions held at New Glasgow, N.S., and Sussex, N.B.

MEETINGS ATTENDED.

Considerable interest has been shown in farm matters; judging from the requests to address agricultural gatherings at different places. Many of these requests could not be complied with, but I have met with the farmers and addressed meetings at the following places during the past year :—

28th December, Truro, N.S.; 4th January, Scotch Hill, N.S.; 12th January, Kingston, N.B.; 13th January, Buctouche, N.B.; 14th January, Fox Creek, N.B.; 17th January, Great Village, N.S.; 18th January, Bass River, N.S.; 19th Brookfield, N.S.; 21st and 22nd January, Antigonish, N.S.; 25th January, Shubenacadie, N.S.; 27th January, Wolfville, N.S.; 31st January, West Bay Road, N.S.; 1st February, Milford, N.S.; 3rd February, Baddeck, N.S.; 4th February, North East Margaree, N.S.; 5th February, Margaree Forks, N.S.; 7th February, Strathlorne, N.S.; 9th and 10th Truro, N.S.; 11th Mapleton, N.B.; 16th, 17th and 18th, Fredericton, N.B.; 21st February, Pugwash, N.S.; 22nd February, River John, N.S.; 23rd February, Durham, N.S.; 24th February, Westville, N.S.; 26th February, Bridgeville, N.S.; 3rd March, Charlottetown, P.E.I.; 4th March, Montague, P.E.I.; 5th March, Murray Harbour, P.E.I.; 8th March, Kensington, P.E.I.; 9th March, Summerside, P.E.I.; 9th March, Tyne Valley, P.E.I.; 10th March, Alberton, P.E.I.; 1st April, Middle River, N.S.

I have the honour to be, sir,

Your obedient servant,

R. ROBERTSON.

REPORT OF THE HORTICULTURIST.

(W. S. BLAIR.)

To DR WM. SAUNDERS,
Director Dominion Experimental Farms,
Ottawa.

SIR,—I have the honour to submit herewith a report of some of the work done in the Horticultural Division of the Experimental Farm for the Maritime Provinces for the year 1898.

The apple crop in Nova Scotia during the past year has been an average one; except in the counties of King's and Annapolis, from which only a fair crop is reported. In New Brunswick the summer and fall crop of apples was up to the average with a fair crop of winter fruit. From Prince Edward Island the report is a fair crop of apples. The first New Brunswick grown apples were exported to the British market this fall, showing that sure progress is being made in that province in the fruit growing industry.

Plums were an average crop throughout the province of Nova Scotia, while in New Brunswick the crop was not up to the average. Pears were not an average crop and the quality was not as good as usual. Raspberries were an average crop in the provinces, and strawberries are reported below the average, both as to yield and quality. Gooseberries were only a fair crop.

A few fruit trees were planted in the orchards on the Experimental Farm at Nappan, to replace some that had died. All the trees have made fair growth and No. 1. orchard produced some well coloured fruit of fair quality, but small. Those planted in Orchard No. 2, where protection is afforded by the shelter-belt of spruces, have made good growth. This orchard is well underdrained, the tiles having being laid 3 feet deep between each row of trees, making the drains 24 feet apart.

A plot of ground to the south of the horticulturist's house consisting of about 1½ acres has been set aside for experimenting with small fruits, vegetables, and other such work coming under the horticultural department. On this new piece of ground new varieties of small fruit have been set out; some experiments have been carried on with different kinds of fertilizers to gain information as to the value of such for forcing vegetables for early market. Experiments have also been conducted with potatoes grown under different modes of treatment. This land is clay loam and had previously been in hay, one-half of this ground was the site of an old orchard which was removed before ploughing in the fall of 1897.

A shelter-belt has been planted along the boundary fence on the south side of the above field. The trees were put in rows 10 feet apart and 20 feet apart in the rows. One row was planted with the heavy-wooded pine *Pinus ponderosa* and one with Norway spruce *Abies excelsa*.

Data on the blossoming period of the different varieties of fruits grown on the farm were again furnished the horticulturist of the Central Experimental Farm.

The ornamental trees, shrubs and hedges have made good growth, and a few new varieties have been added to the list.

The flower garden presented its usual appearance, and the added new varieties of flowers and bulbs helped to make an interesting collection. The Japanese Irises and Pæonies all lived, with the exception of three varieties of each, and although only a few bloomed, they were much admired. Arrangements have been made for an extension in the flower department, which will enable us to show a much larger collection of both annual and perennial flowering plants.

I beg to acknowledge the receipt of a number of seedling apple stocks and scions from Messrs. John Robertson & Sons, Inkerman, New Perth, P.E.I. These were used and the root-grafts have made splendid growth. Three trees of the Banks apple were also kindly donated by A. S. Banks, of Waterville, King's County, N.S., which have been duly planted.

ORNAMENTAL TREES AND SHRUBS.

Year by year we find a growing desire amongst our people to plant around their dwellings and along the road side ornamental trees and shrubbery. Every farmer thinks more or less of planting some trees to make his home more attractive, but the dairy farmer's time is often too fully occupied to attempt planting and caring for any considerable number of varieties. The first step to be taken, and the one too often neglected when planning for the ornamentation of the home in this way, is the preparation of the soil for a nice lawn.

If only a small place is to be planted. the Norway and Sugar Maple, the American and European Elm, the Austrian and White Pine, and the Norway and Black Spruce make very handsome specimens. For larger lawns the above named varieties with the Colorado Blue Spruce, Pyramidal Arbor-vitæ, Purple Birch, White Birch, European Linden, European Mountain Ash, American Ash, Box Elder, English Oak and Red Maple.

In planting trees about a house they should be arranged so as to preserve an outlook when the trees have grown. Imitate nature as far as possible, so that from the windows of the house the view shall be pleasing. Do not plant too close to the house nor overcrowd the lawn. Always bear in mind that the trees are planted to remain, and the planter should have in mind at the time of planting the size the trees will attain when they are 25 or 30 years old, so that the mistake of close planting may be avoided.

Shrubbery may be planted with advantage in groups or clumps 8 to 10 or 12 feet apart along the driveway at points and turns and also at certain positions to form a background. No ground space around a dwelling is so small that some shrubs cannot be used to advantage, and they are objects of great beauty, especially when in bloom. Such varieties as Spiræa Van Houtte, which has drooping limbs covered with white flowers lasting from two to three weeks, Spiræa Callosa Alba ; different varieties of lilacs, such as Josika, Charles X., and the white lilac, *S. vulgaris alba ;* mock orange, *Philadelphus coronarius* and *grandiflora*, weigelia rosea ; Deutzias, especially the variety known as *gracilis*, which is of dwarf habit ; Golden-leaved Elder, *Sambucus Canadensis Aurea ;* purple-leaved plum, *Prunus Pissardi* ; the common snowball, *Viburnum opulus sterilis ;* shrubby cinquefoil, which gives a yellow bloom almost the entire season ; Tartarian Bush Honeysuckles, Japanese and Purple Barberry, Japanese Hydrangea, and Cytisus Purpurea. For evergreens the Dwarf Mountain Pine, the Retinosporas, such as the plumosa, aurea and filifera ; some of the many varieties of arbor-vitæ, such as the Compact, Globose, Hoveyi and variegated, and the Holly Barberry.

The following table gives the present height of some of the ornamental trees and shrubs planted around the superintendent's house in 1891, showing the vigorous growth they have made since that time :—

Ornamental Trees—Planted in 1891.

Name.	Present Height.	Circumference at the Base of Trunk.
	Feet.	Inches.
Norway Spruce—*Picea Excelsa*	13	17

WINDBREAK OF SPRUCE AND PINE.

In the spring of 1891 two rows of evergreen trees were set 10 feet apart along the boundary fence near the orchard. The trees were planted 20 feet apart in the rows, and one row was set with Norway Spruce (*Picea excelsa*) and one with Scotch Pine (*Pinus sylvestris*). They were planted so that one row would break the openings in the other. Back of those and close to the fence, but 15 feet from the row of spruces; hardwood trees were planted 40 feet apart. These trees have made vigorous growth and the space between the rows is now almost entirely filled up. The pines are from 14 to 16 feet high, measuring in circumference at the base of the trunk from 18 to 25 inches. The spruces are from 13 to 17 feet high and the trunks measure from 15 to 18 inches in circumference at the base. The Norway Maples are from 16 to 18 feet high and measure from 14 to 16 inches at the base.

LAWN.

There is nothing so attractive around a place as a good lawn. In order to have such a lawn the ground must be thoroughly worked up and enriched. It is impossible to form a good lawn by simply ploughing up a piece of worn out land and seeding it down to grass. Plough deeply and thoroughly work in a good dressing of well rotted stable manure, then harrow and grade off the land so as to make it as even as possible for seeding. A mixture has been tried here of 5 pounds of Kentucky Blue Grass to 1 pound of White Clover, sown at the rate of 5 bushels per acre, which has made a good lawn. Another mixture for lawn seeding that has given good results is 2 pounds of White Clover to a bushel of half and half Red Top and Blue Grass at the rate of 5 bushels per acre. The Red Top stands drought better than the Blue Grass, but if the land is inclined to be wet or shaded, the first named mixture would probably give the best satisfaction. If not sown thickly, the Red Top is liable to grow bunchy, and make an uneven lawn. The seed should be sown carefully so that a good even growth will be obtained. The best way to cover the seed is to scatter, with a sieve, fine rich earth over it; should it be raked in the greatest care is necessary to get it covered evenly,

after which roll the lawn thoroughly. The best time to prepare a lawn is in the spring and it will require little attention again that season except to keep down any weeds that may grow.

SMALL FRUITS.

A considerable number of new varieties of small fruits, such as gooseberries, currants, raspberries, blackberries and strawberries, have been added this year to those previously grown. The old raspberry plots as stated last year are diseased with anthracnose and new plants were obtained for new plots. It is found that to cut out the canes as soon as they have fruited is the best way to keep this disease in check. The yield obtained from each row in the old raspberry plots is given below. Each plot occupies a space 6 by 132 feet, the rows being 132 feet long and 6 feet apart. The plants were set in the spring of 1894, and have had no manure nor other fertilizer since planted.

The strawberry plots were planted in the spring of 1897 in plots of two rows, each 16 feet long and 3 feet apart. A space of 4 feet was allowed between the plots. The plots were allowed to grow in the matted row system and each plot was squared up to occupy a space $16\frac{1}{2}$ by 6 feet or 99 square feet. The land on which these were grown was manured in the fall of 1896 after ploughing and the manure worked in the following spring. 330 pounds nitrate of soda, 330 pounds fine ground bone and 440 pounds hardwood ashes per acre were sown broadcast on the plots on 29th April. The crop harvested from these plots is given in the table which follows.

The English gooseberries have made fair growth. The mildew has not troubled the plants, and an occasional spraying with Bordeaux mixture has kept all fungous diseases in check. In this fruit the weight of crop given is the average yield per bush of the varieties tested.

Garden Pease.—Test of Varieties.

Twenty varieties of garden pease were sown 17th May. The plots were 4 by 66 feet, on which two rows of pease were sown 6 inches apart and 66 feet long. The land was in poor condition, having previously been in hay. Stable manure at the rate of 25

tons per acre was ploughed under in the fall. The pease on one-half of each of these plots were pulled when fit for market, and the yield of green marketable pease in pods on the whole plot calculated. The other half was allowed to ripen from which the pounds of shelled ripe pease on the whole plot was calculated. The yield from the size of plot as given above was as follows:—

GARDEN PEASE.

Name.	When fit for Market.	Marketable Green Pease in pods. Yield per acre.	Length of Pod.	Number of Shelled Pease in a Pod.	Ounces of Shelled Pease in 1 lb. as pulled.	Pounds of Shelled Pease ripened per plot.	Quality.

GARDEN PEASE.—TREATED IN DIFFERENT WAYS.

In order to gain information as to the value of nitrate of soda for the production of green marketable pease, eight plots were treated differently. The plots were 4 by 66 feet or $\frac{1}{165}$ of an acre, on which 2 rows were planted 6 inches apart and 66 feet long. The plots that were manured were alongside those of the variety test plots and received the same kind of treatment. The piece of land on which the balance of these plots were, had no manure, being left for a road alongside the other plots; but was not used for that purpose. All of the land was fall ploughed. The fertilizer sown when the

seed was planted was raked in by hand, and that sown after the seed was planted was also worked in by hand. The variety Heroine was used. The pease were pulled July 29th, and the yields as given in the following table was obtained:—

GARDEN PEASE.—TREATED DIFFERENTLY.

—	Kinds of fertilizers used and the quantity applied.	Yield of marketable green pease in pod from plot $\frac{1}{165}$ of an acre.
Plot 1	Stable manure and no fertilizers	36 pounds.
" 2	Stable manure and nitrate of soda 330 lbs. peracre	38 "
" 3	No manure. Nitrate of soda 330 lbs. per acre, given in two applications after the seed is planted at intervals of one and two weeks	32 "
" 4	No manure. Nitrate of soda 660 lbs. per acre, given in one application one week after the seed is planted	34 "
" 5	No manure. Nitrate of soda 330 lbs. per acre applied before planting	32 "
" 6	No manure and no fertilizers	28 "
" 7	No manure. Nitrate of soda 495 lbs. per acre applied before planting	30 "
" 8	No manure. Nitrate of soda 660 lbs. per acre applied before planting	30 "

TOMATOES.—TEST OF VARIETIES.

The first tomato seed was sown in the hot-bed 29th March. The plants were transplanted to the cold frame 23rd April, after which it came in cold and the plants all damped off. New plants were started in the hot-bed and these were transplanted when large enough to 4 inches apart in the hot-bed, which by this time contained little heat in itself. The plants remained there until 11th June, when they were set out in the open ground.

Five varieties were planted, one row of each kind 66 feet long and the plants were set 4 feet apart each way. The yield in pounds given is from a plot 4 by 66 feet or $\frac{1}{165}$ of an acre. Stable manure at the rate of 20 tons per acre was ploughed under the previous fall. The crop previously grown on this land was Timothy hay:—

EXPERIMENT WITH CUTTING BACK TOMATO VINES TO PROMOTE MATURING.

In order to test the value of cutting away some of the non-fruit producing branches, so as to hasten the ripening period of the fruit, three hills of the following varieties were

cut back and the same number of hills were left untouched. The hills were treated alike. On 12th September the fruit was picked and the amount of ripe fruit obtained was as follows :—

Variety and how Treated.	Ripe.

I have the honour to be, sir,
Your obedient servant,

W. S. BLAIR,
Horticulturist.

EXPERIMENTAL FARM FOR MANITOBA.

REPORT OF S. A. BEDFORD, SUPERINTENDENT.

BRANDON, MAN., 30th November, 1898.

To Dr. WM. SAUNDERS,
Director, Dominion Experimental Farms,
Ottawa.

SIR,—I have the honour to submit herewith my eleventh annual report, with details of the experiments undertaken and work accomplished on the Brandon Experimental Farm, during the past year.

Although the prospect was gloomy at times, the past season on the whole was a favourable one for the Agriculturist. Spring opened up about the average date and seeding commenced here on the 15th of April and was continued without hindrance until the close of the season. Wind storms were not as troublesome as usual, and no serious injury resulted from spring frosts which were so troublesome in 1897. The months of April and May proved very dry, not a shower falling until 25th of May. For a week or ten days previous to that date, there was very little growth and all grain wilted badly, but from that date onward showers were frequnnt and growth rapid.

Favourable weather continued through remainder of the growing season with the result that nearly all cereal, fodder and root crops averaged the largest ever grown on this farm. Wheat was, however, not as large a crop comparatively speaking as oats and barley, owing no doubt to the rains coming rather late for this grain.

The weather during cutting and stacking was unusually wet; greatly retarding harvest operations, and where stacks were badly built more or less of the grain was injured, fortunately the injury on the Experimental Farm from this cause was very slight.

The kernel of all kinds of grain is this year unusually large, but the colour is not equal to the usual standard. A feature of the year was the excellent quality of the straw, comparatively little of it either rusted or lodged, although the growth was very rank.

Attention is called to the large returns of wheat obtained after a crop of pease and to the fact that formalin has proved successful as a preventive of smut in oats, thus confirming the results obtained at the Central Experimental Farm at Ottawa, last year.

Clover sown without a nurse crop has again successfully wintered and the yield of wheat on clover land promises to be a profitable one. Japanese Millet has given a remarkable yield of fodder, and if its feeding properties are found to be good, it is of promise for this country. Awnless Brome Grass continues to give good results on this farm and reports from parties supplied with seed are generally satisfactory. Fodder Corn gave an abundant yield and reached an advanced stage of maturity. Trees and shrubs of all kinds have made good progress this year. The vegetable garden has given good returns, and a number of varieties of vegetables tested appear to be well suited to this country. Work in all lines on the Experimental Farm is expanding, the number of experiments undertaken being larger than heretofore; new land is being brought under cultivation and larger quantities of grain grown, all of which is in demand by resident farmers for seed purposes. The amount of correspondence is larger and the number of visitors is increasing each year.

EXPERIMENTS WITH WHEAT.

TEST OF VARIETIES.

The soil selected for these tests was not the most suitable for the purpose, being somewhat sticky and lacking in humus. The returns were, however, fair, and the quality of the grain excellent in nearly every instance.

Goose Wheat, the most productive variety this year, also headed the list in 1896. This is a hard flinty wheat evidently very productive here, but is inferior as a milling wheat. It is also later to mature than Red Fife.

Monarch, a beardless wheat, has been among the five most productive varieties for three years. It is a good, bright, heavy sample and would pass readily for Red Fife.

White Fife has now for three years in succession given a larger return here than the Red Fife, the average being about four bushels per acre in favour of White Fife.

Crown, a cross-bred wheat originated on the Experimental Farms, is one of the best bearded varieties grown here, it is productive and of good quality.

Wellman's Fife is very similar to Red Fife, but the head is longer and the kernels not so compactly placed in the ear. Although the head is longer it does not always produce as large a yield as the Red Fife.

A large proportion of those varieties, which gave the smaller crops, were badly affected with rust. The fife wheats are noticeable for their freedom from rust, the White Fife being particularly so.

The land for this test was summer-fallowed the previous year; the size of the plots was $\frac{1}{20}$ acre. The soil was a clay loam and all the plots were sown on 20th April.

Average Results from a Five Years' Test of Wheat.

Only by repeated tests continued through varying seasons can we expect to reach correct conclusions.

For this reason a summary is given of the test of varieties of wheat for four and five years.

Wheat after a Clover Crop.

In the eastern provinces clover has become an important factor in crop rotations, but very little is known regarding its effects in this country.

A plot of land which had been in Sweet Clover for two years, was ploughed last spring and sown with Red Fife. For comparison two adjoining plots one which had been summer-fallowed the previous year and another of wheat stubble, were sown about the same time.

The yield on the land on which the sweet clover was grown, exceeded that from wheat stubble, but was not equal to the summer-fallowed land. The plots were $\frac{1}{20}$ acre each and the soil a rich sandy loam.

How Treated.	Sown.	Ripe.	Character of Straw.	Weight of Straw per Acre.	Yield per Acre.		Weight per Bush.

The Rolling of Land for a Wheat Crop.

One of the objections to the rolling of land in this country after sowing grain is the tendency that finely pulverized soil has to drift with severe wind storms during the spring months, some think that the injury is lessened when the rolling is done before sowing. Owing to an absence of severe storms this year, this point could not be fairly tested.

It will be noticed, however, that rolling in each instance gave enough increase in yield to pay for the extra work, this agrees with the results obtained here from a similar experiment during 1894.

The tests were made on plots of $\frac{1}{20}$ acre, soil sandy loam, and the sowing done with a shoe drill.

The field had been summer-fallowed the previous year. There was no rust on these plots.

Test of Drills for Sowing Wheat.

Each year as the soil on the older fields becomes more finely pulverized, the advantage of drill sowing over broadcast is more apparent.

This year the germination of the broadcast sown grain was delayed so much that the crop was badly frozen by fall frosts, injuring the sample and reducing both the yield and weight per bushel.

The use of drills is now more general throughout the province, but there are a few farmers who still adhere to broadcast sowing, which results in a loss of a considerable percentage of their crop.

The size of the plots was $\frac{1}{20}$ acre each, the soil a sandy loam, which had been summer-fallowed. There was no rust on these plots.

Varying Quantities of Seed for Wheat.

In these experiments five pecks of seed gave the best return during the past season, this is from one to two pecks less than is generally used here.

The size of plots in this test was one-twentieth acre. The soil was a rich, sandy loam, and a hoe drill was used for sowing. The field was summer-fallowed. There was no rust on any of these plots.

Preventives of Smut in Wheat.

Two different classes of wheat were treated with bluestone this year.

The one called "clean" seed had no appearance of smut, but evidently there was sufficient spores to affect the produce.

The other sample was so badly affected with smut that only a very careless person would think of using it for seed. Red Fife was the variety used in each case.

Although bluestone has in most seasons effectively prevented smut, even where the seed was badly affected, the experience of this year would indicate that smutty seed should not be sown, and that apparently clean seed should be treated to secure freedom from smut. The seed in this test was treated with bluestone prepared by dissolving 1 lb of the bluestone in 3 gallons of water and sprinkling this on the wheat before sowing.

The land was summer-fallowed for this test. The size of the plots was $\frac{1}{20}$ acre each, and the soil was a sandy loam. The plots were all sown on the 30th of April.

Different Ways of Preparing Land for Wheat.

The best returns were obtained after pease. This is in accordance with the experience of former years, and is a strong argument in favour of the more extensive cultivation of this crop.

The comparative small yield after flax agrees with the general experience of farmers in this province.

The results from spring and fall ploughing also agrees with the experience gained in former seasons. Spring ploughing appears to be the most advantageous, but unfortunately there does not appear to be sufficient time for the farmer to prepare all his wheat land in the spring, and a portion has necessarily to be ploughed in the fall.

All the plots in this test were sown on 19th April, the size of the plots was $\frac{1}{20}$ acre each and the soil a clay loam.

Results of Early, Medium, and Late Sowings.

This series of experiments has been continued this year with results more than usually instructive.

The returns of wheat were remarkably uniform. In every instance the earliest sown wheat gave the largest crop, the yield gradually growing less from week to week until the small returns of 14⅓ and 16⅔ bushels were reached. The difference between the earliest and latest sown Red Fife was 28⅔ bushels per acre, and with the Stanley wheat 20⅓ bushels.

In nearly every instance the weight per bushel also diminished each week, the difference in Red Fife being 11½ pounds per bushel and in Stanley 13 pounds.

The two first sowings of each variety were only slightly injured by rust, while the later sown plots were seriously affected.

The last sown plot of each variety was injured by fall frost.

The land for this test was summer-followed, the size of the plots was $\frac{1}{20}$ acre each, the soil a rich black sandy loam.

OATS: EARLY, MEDIUM AND LATE SOWINGS.

The results with oats were also fairly uniform, but the second sown plot gave the largest return with both varieties, this agrees with the experience had in former years.

The difference in yield between the second and the last sown plots of Abundance oats was 50 bushels per acre, and with Banner 58 bushels, a very strong argument in favour of early sowing. The quality of the grain from the last sown plot was very inferior and light in weight.

The size of the plots was $\frac{1}{20}$ acre each, and the soil a rich black loam, which had been summer-fallowed.

BARLEY: EARLY, MEDIUM AND LATE SOWINGS.

With barley the advantage of early sowing was not so apparent as with the other grains noted, and it would appear that this cereal can be sown in this climate later than either wheat or oats, without much loss.

The size of the plots was $\frac{1}{20}$ acre each, and the soil a rich black loam, which had been summer-fallowed.

Pease: Early, Medium and Late Sowings.

Usually early sown pease give the best returns, but this year the third and fourth sowings have produced the largest yields. This result can be attributed to the fact that the spring rains came much later than usual.

The size of the plots for this test was $\frac{1}{20}$ acre, the soil a rich black loam which had been summer-fallowed.

EXPERIMENTS WITH OATS.

The importance of this cereal for feed to the farmers of Manitoba should result in greater care in the preparation of land for this crop.

The very general plan of sowing a field with wheat as long as it will bear a crop and following this with oats may prove fairly successful in a year of heavy rainfall, but will surely lead to disappointment in a dry season.

As a rule in Western Manitoba no more than two crops of wheat in succession should be grown after a fallow, and on some soils one crop of wheat followed by oats or barley will be found the most profitable.

The past season has been a very favourable one for oats and the yield on all parts of the experimental farm has been unusually large and the quality excellent.

American Beauty is an excellent variety of white oats which has been very productive on this farm.

California Prolific Black was among the ten most productive sorts in 1897, and has again given good returns in 1898.

Bavarian has also proved very productive on large fields as well as in plots, this year.

Mennonite is maintaining its reputation as one of the best yielding varieties here, but its yellow colour is often objected to. This variety was imported by the Mennonites from Russia some years ago and received from them the name of Russian oat.

Oxford and Pense are both cross-bred white varieties with half-sided heads and bright stiff straw.

The large yield of 106 bushels of Banner Oats show that this is still one of the best sorts for general cultivation in this province.

To prevent smut the seed of all the varieties was immersed for five minutes in a liquid composed of one pound of bluestone dissolved in three pails of water.

Seven of those so treated were considerably affected with smut and four slightly so, the remainder were quite free from this disease.

These tests were made on plots of $\frac{1}{20}$ acre, the soil was sandy loam summer-fallowed, two bushels of seed was used per acre sown with a shoe drill and all the plots were sown on the 30th of April.

Average Results of Four and Five Years' Tests of Oats.

The accompanying table shows that the Banner Oat still takes the lead, and the difference in average productiveness of the several varieties is very marked.

The report for 1896 showed that the average return from Black Tartarian up to that date was 26 bushels per acre less than the Banner, and this year the difference is still over 20 bushels in favour of the Banner, and the Tartarian is seven days later in ripening.

Oats.—Test of Varieties Sown on Spring Ploughed Stubble.

Many farmers contend that Banner Oats may possibly excel Black Tartarian on summer fallow ; but on spring ploughed stubble the Tartarian is the most productive. Last year these two varieties gave exactly the same yield on stubble land, but this year the Banner gave over 16 bushels per acre more than the Tartarian.

The Banner is not only a better milling oat but is more productive than the Tartarian.

The size of the plots used for this test was $\frac{1}{10}$ acre, the soil a clay loam and all were sown May 21st.

Oats and Pease Mixed for Grain.

For several years oats and pease mixed have been grown on this farm for fodder, but this year they were sown with the object of ripening the seed. With one exception the plots having the larger proportion of oats, gave the largest crop of grain.

The yields have been estimated on a basis of 40 lbs. per bushel.

The size of the plots in this test was $\frac{1}{20}$ acre and the land was summer-fallowed :—

Formalin and Bordeaux Mixture as preventives of Smut in Oats.

While immersion in a weak solution of bluestone is useful in checking the spread of this disease, this treatment does not destroy all the spores in a badly affected sample, and some more efficacious remedy is desired.

For this experiment three varieties of very smutty oats were selected.

Two samples of each sort were treated with formalin ; one sample being steeped for two hours in a mixture composed of 3 oz of formalin to 10 Imperial gallons of water, equal to 2 to 1,000, and the other consisting $4\frac{1}{2}$ of formalin in 10 Imperial gallons of water or 3 to 1,000.

Bordeaux mixture (4 lb. lime, 4 lb. bluestone, in a barrel of water) was also used for this purpose, the seed being soaked for four hours in this preparation.

Check plots were sown with each variety of oat, untreated.

Each plot, was examined carefully and not a smutty head could be found on any part of the plots sown with seed soaked in the formalin solution for two hours.

From the foregoing it would appear that the steeping of badly affected oats for two hours in a solution of formalin is a comple preventive of smut. But there are objections here to steeping grain for that length of time.

The quantity of seed used by each farmer is large, and the expense of providing vessels for this purpose is an important item. Further there are few facilities here for drying large quantities of grain and the time required is quite a consideration in the rush of spring work.

For these reasons it was thought advisable to try steeping in the Bordeaux mixture and formalin for shorter periods. The variety of oat used for this test was Doncaster Prize, a very smutty sample, grown on this farm in 1897. The sample used in the former trial was sent from Ottawa by the Director with the formalin and the instructions for using.

From the annexed table it will be noticed that the untreated sample gave about one half smutty heads, that the seed treated with Bordeaux mixture was very little better, but that the plots treated with formalin even for 5 minutes were quite free from smut ; it seems probable that a steeping for five or ten minutes may prove sufficient.

Should this prove sufficient, the time and expense required for the treatment of a large quantity will be much reduced, as the seed can be bagged at once and sown in a few hours without drying.

FORMALIN AND BORDEAUX MIXTURE as smut preventives,—grain steeped for short periods.

Variety of oats.	How Treated.	Time Steeped.	Good Heads.	Bad Heads.
Doncaster Prize	Untreated		163	142

"	" "	30 "	325	0

The solution of formalin used in each of the above tests was made by mixing 4½ ounces of the formalin with 10 Imperial gallons of water.

Barley—Test of Varieties.

The season has been a favourable one for barley, and the yield averages higher than usual. The weight per bushel is in nearly every instance above the standard. The colour was, however, badly injured from excessive rains when in the sheaf.

The six-rowed varieties were stiffer in the straw than the two-rowed, about 66 per cent of the two-rowed being more or less lodged, while only 25 per cent of the six-rowed proved weak in the straw.

The size of the plots used for this test, was $\frac{1}{20}$ acre, the soil a sandy loam which had been summer-fallowed, and the plots were all sown on the 13th of May.

Pease—Test of Varieties.

The season has been a favourable one for this crop, and both yield and quality was good. Owing to the rain coming late in the season, many plants made a second growth, resulting in a large proportion of green pease in the sample. As better results seem to be obtained with pease on the Experimental Farm, than on the average farm of the province, a short description of the plan of growing pease here may prove instructive.

The strongest soil is selected for this crop, usually stiff clay loam. The field is well summer-fallowed the previous year, and is not harrowed in the spring before sowing. The grain is always sown as early as wheat, and with a drill, as deeply as possible, from $2\frac{1}{2}$ to $3\frac{1}{2}$ bushels of seed per acre is used, the larger the pea the more seed is required.

If the crop is to be cut with a binder, two pecks per acre of oats are sown with the pease.

The size of the plots for this test was $\frac{1}{20}$ acre, the soil a stiff clay loam, summer-fallowed, all the plots were sown either on the 24th or 29th of April.

Average results from a five years test of Pease.

The variation in yield is not so great with different sorts of pease as with some other crops, still the difference of eight bushels per acre in the average yield of varieties for this period shown in the accompanying tables is worth considering. None of the new cross-bred sorts, some of which are very productive, have been long enough in cultivation here to be included in this list.

EXPERIMENTS WITH FLAX.

The yield of both flax seed and straw was abundant this year, but it was found difficult to secure the crop, especially where the sowing was late, and large quantities were still lying in the fields throughout the province when the first snow fell. On this farm the usual tests of thick and thin, and early and late sowings have been repeated.

The largest average yield of seed was obtained from the last sown plot, and the best return of pulled straw from the sowing of 21st May.

The thick sowings have given the largest average return of pulled straw and the smallest amount of seed.

All these plots were sown on rich black loam, which had been summer-fallowed, the size of the plots was $\frac{1}{20}$ of an acre.

ROTATION PLOTS.

As yet very few farmers have any regular rotation in sowing their crops, but sooner or later some regular system suited to the requirements of the several districts, will need to be adopted. With a view of throwing some light on this subject, a number of plots on the Experimental Farm have for some years been devoted to this test. The accompanying table gives the results of four years work on this line, from which it will be seen that wheat alternated with roots or corn has given the largest money returns, but in this case the outlay was proportionately large.

The second plot in the list which was sown to wheat and oats on alternate years, shows a good return but the land has now become very weedy and the sample is badly mixed each year; from volunteer grain.

The plot sown with wheat continuously still gives a very fair yield, but the land is becoming more and more weedy each year. In every instance the summer-fallowed plots show the least number of weeds and should we have a succession of seasons with light rainfall, the yields on the fallowed land would be proportionately larger.

For comparison the price of wheat has been placed at 50 cents per bushel, oats 25 cents and barley 25 cents, turnips 5 cents per bushel and fodder corn at two dollars per ton.

All but the summer-fallowed land was ploughed in the spring.

The size of the plots in this test was $\frac{1}{10}$ acre, the soil an average sandy loam.

EXPERIMENTS WITH INDIAN CORN.

Although the early part of the season was unfavourable for the rapid growth of corn; the weather during July and August was all that could be desired for this crop, and the yield of nearly all varieties is above the average, frost also kept off sufficiently late to allow many of them to reach an advanced stage of maturity. Such rank growing sorts as Red Cob Ensilage and Cloud's Early Yellow reached the early milk stage, and many ears of North Dakota Flint were fully matured.

With but two exceptions the yield from rows exceeded that from hills, this agrees with the experience here in former years.

In addition to the varietal test of fodder Corn experiments were made in sowing at different distances apart. In two of the three varieties tried the largest yield was obtained from rows two feet apart; this is one-third closer than is generally recommended, such experiments need to be repeated for several years before any safe conclusion can be drawn from them. The corn also would probably be more mature in the wider rows.

Seven acres of North Dakota Flint corn was grown for ensilage, this field was spring ploughed wheat stubble. A considerable quantity of volunteer grain and weeds came up among the crop, but these were readily kept in check by harrowing every few days until the plants were three inches high. The one horse cultivator was then twice run lengthwise of the rows, followed each time by a clean hoeing between the plants, and the field by this means was kept quite free of weeds. The yield was 11 tons per acre of corn, which was cut on an average four days before weighing; this partial drying before putting it into the silo ensures an excellent quality of ensilage. If not partially wilted the ensilage is nearly always sour in this climate.

The soil was a rich black loam; all the varieties were sown on 23rd of May, and the yield per acre has been calculated from the weight of crop cut from two rows each 66 feet long.

The previous crop was potatoes.

EXPERIMENTS WITH FIELD ROOTS.

The abundant rain-fall during the late summer and fall, was very beneficial to the field roots and produced a rapid growth of the plants.

The yield has been a phenomenal one, far exceeding any previous crop on this farm, and the quality excellent.

In addition to the usual test of varieties on fall ploughed land, duplicate plots were sown on summer-fallow, and in nearly every instance the returns from summer-fallow exceeded those from fall ploughing.

TURNIPS.

As usual here the Purple Top Swede has proved the most productive both on summer-fallow and fall ploughing ; this is also an excellent Swede for table use.

Hartley's Bronze is another variety which has grown a large crop, and both of these can be recommended for this province.

The soil was a rich sandy loam ; the estimate of yield has been made from the product of two rows each 66 feet long ; all were free of rot.

The first plots were sown on 17th May and the 2nd on 1st June in drills 30 inches apart ; all were pulled on 7th October.

The previous crop on the fall ploughed land was mangels.

EXPERIMENTS WITH MANGELS.

This excellent field root can generally be depended upon to produce a paying crop here, it is less liable to injury from insect enemies than any of the other root crops, gives a larger yield per acre, and is prefered by milch cows, young cattle and swine.

The soil on which these roots were sown was a rich clay loam, and the estimate of yield has been made from the product of two rows each 66 feet long.

The first plot was sown on the 17th May, the second on the 1st June, in drills 30 inches apart; all were pulled on 4th October.

EXPERIMENTS WITH CARROTS.

Although duplicate plots of carrots were sown, as of the other field roots both on summer-fallow and fall ploughing the former suffered so badly through imperfect germination of the seed, that the returns would be quite misleading and hence are not given.

The soil of the fall ploughed field was a rich clay loam, the previous crop was mangels, and the estimate of yield has been made from the product of two rows each 66 feet long. The first plots were sown on 17th May, the second on 1st June, in drills 18 inches apart, and all were pulled on 11th October.

EXPERIMENTS WITH SUGAR BEETS.

The following are the yields obtained from six varieties of sugar beets sown at two different dates on rich clay loam both on summer-fallow and fall ploughed land.

The first plots were sown on the 17th May, the second on 1st June. All were pulled on 4th October, and the yield per acre has been calculated from the produce of one row 66 feet long.

EXPERIMENTS WITH POTATOES.

The season has been a favourable one for a large yield of potatoes and the size of the tubers was uniformly large, but the quality is below the average, and many varieties usually of good quality are this year wet and poor in flavour; there were no rotten potatoes and very few scabby ones.

The land selected was in corn last year, and was ploughed deeply in the spring and well harrowed. It was again ploughed shallow on 16th May, and the tubers cut in pieces with 2 or 3 eyes each ; were planted a foot apart in every third furrow.

Very little hoeing was required, as weeds were kept down, principally with the harrow and cultivator.

The following varieties have proved among the most productive during the past two seasons ; Seedling No. 7, Late Puritan, Brown's Rot Proof, Dreer's Standard, and Chicago Market.

The following kinds germinated unevenly, and hence the returns given from them are not a fair test of their productiveness ; Early Rose, New Queen, Everett, Ohio Junior, Early Harvest, Lightning Express, Early Sunrise, Beauty of Hebron, Early Ohio, Burpee's Extra Early, Pearce's Extra Early and Honeoye Rose. Three of these same varieties germinated badly last year, nearly all of them are early maturing kinds. They may have been injured through excessive sprouting before the planting.

The yield per acre has been estimated in each case from the product of one row 66 feet long.

Practically all were marketable.

All the varieties were planted on 16th May in rich sandy loam soil, without manure, and were dug on 4th October.

Grasses and Clovers.

The past season has confirmed previous results, with regard to the growing of grasses and clovers and added some fresh information on a few lines.

Many inquiries have been received in regard to the possibility of growing Brome grass on lands which are flooded for part of the year, and an experiment was tried to gain information on this subject.

A small area on the uplands on the experimental farm, about an acre is flooded from two to four feet deep each year, the water remaining on it until June. This was broken up during the summer of 1896, and sown to Brome grass without grain, a good stand was obtained and a magnificent crop of grass gathered this season, about 3 tons per acre, with a heavy aftermath. This experiment should be tried by farmers who have depressions on their land known here as pot holes, which are numerous in some parts of the province.

A three acre field of Brome grass broken up in August of 1896, and backset in October gave a fine crop of hay this year; the summer breaking apparently proving a benefit instead of killing the plants.

The five acre field of Brome grass ploughed thinly with a breaking plough, early in May, 1897, and backset before harvest, gave a good crop of wheat this year, and there are no signs of living grass plants, but the soil is full of dead roots for ten inches below the surface, and there will be no danger of this land drifting for some years.

Although the dry spring prevented a large return of hay this year, the series of plots sown with grasses were very uniform in character, and show that a fair yield can be obtained even in an unfavourable season. The plots were from $\frac{1}{10}$ to $\frac{1}{20}$ acre in size, and were divided into three series.

First,—A test of varieties sown in June on spring ploughed stubble.

Second,—The same varieties sown on summer-fallowed land in August.

Third,—A series of plots sown with varying amounts of seed.

All the plots were sown during 1896, and without a nurse crop of grain, all weeds and volunteer grain were mown twice during the first summer, and the ground in most cases was well covered with stout healthy plants by fall.

It will be noticed that grasses sown on summer-fallow which were so badly injured by winds last year, gave the best returns this year.

Last season the thick sowing of grass seed gave the largest average yield, while this year the best average is from thin sowing.

The Clovers have again wintered well, and have all given better returns than last year. Alfalfa takes the lead, as before, but Red Clover has improved wonderfully.

It would appear that past failures in growing clovers here may be largely attributed to sowing them with grain crops. The few surviving clover plants among a grain crop have usually very short roots, while this years Common Red Clover plants sown without a nurse crop, had roots eight inches long by fall, and the Alfalfa 16 inches.

Much larger areas were sown with clover last spring, and the ground is now covered with a healthy growth of plants.

Experiments with Grasses on Summer-Fallow.

Test of varieties sown in August, 1896. That year's crop was badly injured by drifting soil.

Grass Seed Distribution.

The demand for grass seed during the past season greatly exceeded the supply. Two hundred and twenty-six one-pound packages were sent out in the free distribution, and forty-seven lots of about fifteen pounds each were sold.

Experiments with Fodder Crops.

Early in the season, seed of Japanese Millet, Early Soja Beans and Horse Beans were received from the Director with instructions for sowing. The chief object in view in these tests was to gain information as to the relative usefulness of these plants for fodder purposes in this climate, and to ascertain the weight of crop obtainable from each when sown in different ways.

Japanese Millet.

This variety of Millet gave large crops and is quite promising.

The season was very favourable for millets, and the yield unusually large. Some of the plants were, however, quite coarse and woody in texture.

The size of each plot was $\frac{1}{20}$ acre; the soil a rich clay loam, and the land had been summer-fallowed the previous year. The seed did not ripen, although many heads were formed.

Yield of Japanese Millet Sown at Different Distances.

Variety.	Width of Drill.	Sown.	Length of Head.	Cut.	Height.	Yield per Acre, Dry Hay.	
						Tons.	Lbs.
Japanese Millet	9 inches	May 27	4 inches	Sept. 5	4 ft. 9 inches	5	1,400

"	Broadcast	" 27	4 "	" 5	4 " 9 "	5	1,200

Early Soja Beans.

This plant can probably be utilized as a soiling crop also for hay and ensilage. During the past season the Early Soja Beans have not proved as productive as horse beans here.

The land was summer-fallowed and harrowed in the spring before planting. The seed was sown with a garden drill and kept clean by the occasional use of a cultivator. The soil was clay loam.

The size of each plot was $\frac{1}{20}$ acre. There were only a very few plants with pods on, and the pods were only partly grown.

YIELD OF EARLY SOJA BEANS SOWN AT DIFFERENT DISTANCES.

"	3 "	3 " 3 "	" 5	7	1,400

HORSE BEANS.

The seed of this useful leguminous plant is utilized largely for horse feed in Europe. The plant can also be used for ensilage or for soiling purposes.

The land for this crop was summer-fallowed and harrowed in spring just before planting.

The seed was sown with a garden drill and kept clean by means of a cultivator; the soil was a rich clay loam. The beans were planted two inches apart in the row, on May 23rd.

The size of each plot was $\frac{1}{20}$ acre. The plants were well covered with pods, nearly all of which were filled with matured beans.

YIELD OF HORSE BEANS SOWN AT DIFFERENT DISTANCES.

EXPERIMENTS IN FEEDING STEERS.

In 1895, a test was made on this farm of the feeding value of marsh hay, as compared with oat sheaves; this year marsh hay was fed in comparison with mixed straw.

For this purposes, eight Shorthorn grade steers three years old were purchased, in December, 1897, at 3 cents per pound live weight, and sold in April at 4 cents.

The steers were divided into two evenly matched groups of four each, and fed all they would eat clean of the following rations.

First Lot of Steers.

	Lbs.
Native marsh hay cut	20
Swedish turnips	30
Barley chopped	3 to 7

Second Lot of Steers.

	Lbs.
Mixed straw cut	20
Swedish turnips	30
Barley chopped	5 to 9

The first lot of steers were fed three pound of grain per day for the first four weeks, and the second lot five pounds per day, thus compensating for the difference in quality of fodder, this amount was in each case increased by two pounds each month, until the maximum of 7 and 9 pounds respectively was reached.

The actual amount and estimated value of the feed consumed per head during the feeding period of 112 days, was as follows.

First lot of Steers.

2,166 lbs. native hay, at $5 per ton	$ 5 41
44 bushels turnips, at 5c. per bush	2 20
622 lbs. chopped barley at ½ cent per lb	3 11
	$10 72

Second lot of Steers.

2,160 lbs. mixed straw.	
45 bushels turnips at 5c per bush	$ 2 25
860 lbs. chopped barley at ½ ct. per lb	4 30
	$ 6 55

Summary of Results.

—	First cost of Steers per head.	Value of feed consumed per head.	Average price sold for per head.	Profit per head.	Average daily gain per head.
	$ cts.	$ cts.	$ cts.	$ cts.	Lbs. oz.
First lot of steers fed with hay	36 10	10 72	54 36	7 54	1 6
Second lot of steers fed with straw	35 62	6 55	53 08	10 91	1 4

The margin between the fall and spring prices of cattle last season was much less than usual, and for that reason the profits of stall feeding was greatly lessened.

From the foregoing tables it would appear that hay is not essential to the successful fattening of steers, and our numerous wheat farmers can utilize to good advantage a portion of their straw for that purpose.

SWINE.

The herd of swine on the farm still continues in good health, and consists now of the following animals :—

Name.	Breed.	Age.
Sir Richard, boar	Berkshire	2 years.
Lady of Brandon, sow	"	6 months.
Crocus of " "	"	6 "
Boar (not named)	"	
Amber Belle, sow	Tamworth	3 years.
Dunrobin, boar	"	18 months.
Amy's Choice 2nd, sow	"	7 "
Brandon Belle "	"	2 "
Squire, boar	Chester White	18 "
Nelly, sow	"	9 "

POULTRY.

Only two breeds of poultry are now kept on the Brandon Experimental Farm—Plymouth Rocks and Black Minorcas.

By limiting the number of breeds to two, more room is left for experiments each year. Both breeds have been perfectly healthy, none having died during the year.

Pullets Compared with Old Hens as Layers.

It is generally thought that too many old hens are kept on the average farm, thus reducing the number of eggs, especially during the winter months.

With the object of testing this matter two pens each containing 11 birds were made up.

Hens.—7 Black Minorcas, 2½ years old.
4 White Plymouth Rocks, 2½ to 4 years old.
Pullets.—7 Black Minorcas, 6 months old.
4 White Plymouth Rocks, 6 months old.

How they were Fed.

Morning meal: equal parts of mixed crushed grain, and 1 oz. of cut bone per fowl; mixed and fed moistened.

Evening meal: ½ wheat screenings, ¼ oats, ¼ barley, all fed whole.

Results.

Number of eggs laid from 4th January to 4th March:

	Eggs.
Pullets	144
Hens	105
Pullets over hens	39

Bone as an Egg Producer.

It is very generally conceded that the feeding of green cut bone materially increases the number of eggs laid, especially during the winter months.

To test this two pens were made up, each consisting of 3 Plymouth Rock pullets and 3 Black Minorcas, all six months old.

How they were Fed.

Pen 1.—Morning meal: equal parts of bran and mixed crushed grain, and one ounce of green cut bone per fowl; the above was mixed together and fed moistened. The evening meal consisted of ½ wheat screenings, ¼ oats, and ¼ barley, all fed whole.

Pen 2.—Received the same food, except that the bone was omitted.

Result.

Number of eggs laid from 4th January to 4th March:

	Eggs.
Pen 1.—Fed green crushed bone	83
Pen 2.—Without bone in their food	52
Gain from using bone	31

Fattening Poultry.

The experiment given on page 333 of last year's Annual Report was repeated in some of its details this year, an effort being made to ascertain the cost per pound of gain in one month when chickens are fattened in pens.

	Lb.	Oz.
Oct. 25th—Weight of 4 Plymouth Rock chickens penned...	16	14
Nov. 25th— " " " ...	22	04
Gain	5	06

Feed consumed.—7½ lbs. wheat, 3¾ lbs. oats, 3¾ lbs. barley.

	Cents.
Value of grain at 1c. per lb.....	15
Cost of feed per pound of gain in one month.....	3

The grain was crushed and moistened for the morning meal, and fed whole for the evening meal.

BEES.

The four hives of Italian bees remaining on hand last fall, were placed in the cellar of one of the farm dwellings on the 4th of October, the usual time in this latitude. But the fall being an open one the bees were quite restless until about the 4th of November, when the temperature in the cellar fell to about 55° F., and after that they were quiet. The evil effects of the high temperature in October was quite noticeable, particularly in the stronger colonies where they were somewhat crowded, and a much larger number than usual died during the winter.

They were placed on the summer stands on the 14th of April, two weeks earlier than in 1897. Native willow again furnished the first honey and pollen.

The spring and early summer were favourable for honey gathering, but the late summer and fall months were both cloudy and wet, and very little honey was gathered in these months.

An average of 53 pounds of extracted honey was taken from each of the four hives, which was sold for 10 cents per pound wholesale.

Three new swarms were hived, one of which was sold leaving six on hand at this date.

The bees were kept on the summer stands until November 11th this year, by which time the cellar temperature had fallen to 47. So far they have remained perfectly quiet.

LARGE AND SMALL FRUITS.

Wild Crabs of Siberia.

The orchard devoted to these trees has received additions from time to time, since 1890.

Pyrus baccata aurantiaca again gave a crop of small fruit. Other and more recently planted varieties, viz. :—*P. B. cerasiformis*, *P. B. macrocarpa* and *P. B. edulis* for the first time flowered this season, but the blossoms proved abortive. The season being propitious, the trees are in a fine condition for the production of fruit next year.

Crab Apples.

The crab apples now undergoing test are *Quaker Beauty*, *Melonen*, *Gideon*, *Jumbo*, *Martha*, *Snyder*, *Yellow Siberian* and *Transcendant*. The last mentioned has been grown here nine years but has been more or less injured by frost each winter.

STANDARD APPLES.

The two *Tonka* and two *Wealthy* trees mentioned on page 336 of last year's report, came through last winter successfully, and this season they have made a strong and healthy growth.

CROSS-BRED APPLES.

The want of success in finding apples sufficiently hardy to endure the climate of the higher altitudes of this province has led to the breeding of varieties by cross fertilization at the Central Experimental Farm at Ottawa. The first consignment of these cross-bred varieties was received on 4th April, 1898, in good condition, and planted in an orchard prepared for that purpose. Some of these were one year old seedlings and some newly grafted stocks.

It was thought advisable to plant them all in permanent position, so that no check would result from further transplanting.

The situation was rather open, and very dry weather setting in coupled with high winds caused the soil to drift, this cut off some of the young and tender shoots as they appeared. From the following record it will be seen that this experiment has thus far been attended with fair success.

Number received.	Record Number.	Female Parent.	Male Parent.	Seedlings or Grafted Stocks	Number Alive.	Number Dead.	Remarks.

White Willow (*Salix alba*) height 17 feet, circumference near base 26 inches, growing on Experimental Farm at Brandon, Manitoba, nine years planted. [305]

PEARS.

One Longworth pear was planted in 1897. It became well established, but like all other trees of this fruit, it succumbed to the first winter's frost.

Pyrus betulæfolia. This was received from the Central Experimental farm last spring; it is said to produce a very small fruit, but if hardy it may be useful for future selection and crossing.

PLUMS.

Last winter was very disastrous to the varieties of improved American plums received from Charles Luedloff, of Carver, Minnesota, in the spring of 1896; these have had a very fair test, specimens of all becoming established the first summer. They were more or less injured by frost the first winter, but the trees being then very small and the snow fall of that winter unusually heavy, they were completely covered and many survived the first year. In the spring of 1897 it was found that, of 72 trees including 36 varieties planted in the spring of 1897, 4 varieties were dead, 18 killed to the ground; 7 were slighty killed back and 7 were apparently hardy; of these 3 had some bloom but no fruit. On the count being taken last spring, 1898, only 9 trees of 7 varieties were found living, leaving 63 trees of 29 varieties that have succumbed to the severe frost and slight snow covering of last winter.

The seven surviving varieties are:—

Variety.	Number planted.	Number alive.	Remarks.
Richland	2	2	Weak growth; killed back.
City	2	2	Fair growth; killed back.
Dunlop Nut	2	1	Weak growth; slightly killed back.
Speer	2	1	Strong growth; not killed back.
Van Deman	2	1	Fair growth; slightly killed back.
Gaylord	2	1	Weak growth; badly winter killed.
New Ulm	2	1	" "

The orchard of plum seedlings received from the Central Farm at Ottawa in 1893, have made a good growth, they have now an average height of six feet, and seem very healthy and vigorous.

This orchard contains 127 seedlings of Weaver, 12 seedlings of Cheney and 34 American seedlings. Many of these fruited for the first time this year. Those that fruited are:—11 trees of Weaver, 1 of Cheney, 2 of DeSoto and 1 of American seedling. This fruit was fair in size, but, although the frost came later than the average season, none of it matured, and when picked on 1st October the specimens were found to be pithy, and devoid of flavour; evidently having been frozen by the severe fall frosts before being fully ripe.

Two of the consignment of unnamed plums received from Mr. Thos. Frankland, of Stonewall, Manitoba, also fruited this year. One of these had fruit of a fine egg shape, but like the others they did not mature before they were injured by frost.

NATIVE PLUMS.

The trees of the native seedling plums that were old enough have again given a large crop of very fair fruit, averaging 10 quarts from each tree. These were ripe on 1st September, and were not injured in the least by the slight frost previous to that date.

The work of propagation is still going on with this plum, and some good results have already been attained.

One Aiken and three Hoskin plums were received from the Central Farm in the spring of 1897. The Aiken succumbed the first winter; one Hoskin survived but was killed to the ground and is by no means promising.

The additions to the list of plums this season are—

Seedlings of Wyant.
do Forest Garden.
do Rollingston.
do Hawkeye.

Cherries.

In the spring of 1895 there were sent from Ottawa 5 each of 6 varieties of cherry seedlings; these have survived two winters, but none of them have as yet fruited.

They are herewith listed with notes:—

Name of Variety.	Number received.	Number alive.		Remarks.
	1895.	1896.	1897.	
Seedlings of—				
Bessarabian	5	4	4	Alive to tips; small growth.
Montmorency	5	5	5	" "
Red Morello	5	5	4	Killed to near ground; large growth.
Wragg	5	4	3	" fair growth.
Olivet	5	5	5	Alive to tips; small growth.
Carnation	5	5	5	Slightly killed back; small growth.

Rocky Mountain Cherry.

Fifteen bushes of this cherry were received and planted in 1895. They are all alive at this date, and have borne a small amount of fruit. They are evidently a variety of the sand cherry *Prunus pumila.*

Prunus Mackii and *Prunus Padus* were two cherries received from Prof. Budd in 1894. Specimens of each of these fruited this season; the fruit is small and astringent, and is of no value as an edible fruit. The trees are useful, however, for ornamental purposes.

Wild Cherry from Nebraska.

Three of these were received from Ottawa in the spring of 1896. They are quite hardy and have made a strong growth, but have not yet fruited.

Compass Cherry.—Two trees were received this spring and have become well established. This is said to be a cross between the Sand Cherry and the American Plum, having some characteristics of each, and is spoken of highly. It is hoped it will prove hardy here.

Sand Cherry.—In the spring of 1894, 200 seedlings of the eastern form of this cherry were received from Ottawa. These have not been hardy with us as yet, and have been killed to the snow line each winter, but having a recumbent habit many of the branches lay below the snow; on these branches fruit was set on nearly all the trees for the first time this season.

They were inspected individually, and out of the 200 trees only two yielded fruit that was up to the standard of fruit obtained from the selected forms of our native Sand Cherry, and many were too late to be of value here.

Manitoba Sand Cherry.

On the Director's annual visit of inspection last August, another one, out of many seedlings of this native cherry was pointed out as worthy of a name and of propagation. It was named and described by him as follows :—

Champion.—Large, very dark red, nearly black when ripe ; flesh sweet and nearly free from astringency, $1\frac{7}{8}$ inches in circumference ; quality good, quite ripe 25th August.

The *Minnie*, *Brandon*, *Othello*, *Standard*, *Progress* and *Challenge*, named varieties of this cherry, are being propagated by layering, and are being gradually disseminated throughout the province.

Grapes.

Three varieties of grapes were planted in the spring of 1895, and have survived three winters. Two of these were received from Ottawa, viz.: *Gibb* and *Bacchus* ; they have made only a small growth, and have as yet given no signs of fruit. The third variety is the native wild grape, which has made a very strong growth, it flowered this season, but the flowers proved to be imperfect, all being staminate, and hence this variety is of no value.

Wild grape cuttings and roots have been procured from many different sources, in Manitoba, with the hope of finding some with perfect flowers.

Currants.

The currant crop this year was an average one, all the old varieties fruiting fairly well. At this time there are 40 kinds undergoing test, and valuable facts in reference to their hardiness and quality are being compiled.

Fertile d'Angers,—a red currant, which is well worthy of special notice. The berries are as large as Fay's Prolific (one of the largest of red currants) but the bunches are larger and better filled than that variety.

If this variety continues to do as it has done the past season it will be a great acquisition to this province.

The *White Dutch* was the only new white currant tested. This is not by any means superior to the White Grape, but being much later than that variety it will be useful for a succession of fruit.

The *Climax* spoken of in previous reports still holds a prominent place among the black varieties.

The *Eclipse*, a black currant seedling from the Central Farm, has fruited this year for the first time, and gives great promise of future usefulness.

Missouri Tree Currant—black. More fruit was picked from this than from any other variety during the past season, and in size, colour and habit it is unique among currants ; it has a peculiar flavour, and cannot be recommended for extensive planting, but a few bushes would be an acquisition to every garden. The bushes are hardy and seem to be well adapted to this climate.

The following varieties fruited here for the first time this season.

Variety.	Flavour.	Colour.	Size.	Earliness.	Productiveness.	Remarks.
Fertile d'Angers	Very good	Red	Very large	Late	Good	Vigorous growth.
North Star	Fair	"	Medium	Early	Poor	Very vigorous.
White Dutch	Good	White	Large	Late	Fair	Slightly tender.
Sterling	Fair	Black	"	Medium	Good	Very vigorous.
Perry	Poor	"	Small	Early	Poor	Generally poor.
Madoc	"	"	Fair	Medium	"	Healthy.
Eclipse	Very good	"	Large	Early	Good	Vigorous.
Lewis	Poor	"	Medium	Very early	Fair	"
Stewart	Good	"	Fair	"	Good	Very healthy.
Star	"	"	Large	"	"	"

Gooseberries.

The native sand hill gooseberies fruited well this year, and have been increased largely by cuttings. Seed of the very finest fruit was selected and sown, and it is hoped by this means to improve this desirable native fruit.

Six each of 10 new varieties of gooseberries were received from the Central Experimental Farm and planted in the spring of 1897; they made a fine healthy growth that season.

No winter protection was given them and this spring most of the bushes were found to be more or less injured and many were killed outright.

The survivors are being treated this year in the same way as the raspberries :—namely by laying them down and covering them with earth, and it is hoped by this means to bring them safely through the coming winter.

List of Gooseberries tested one winter.

Name of Variety.	No. planted.	No. alive.	Remarks.
Industry	6	2	Good summer growth.
Keepsake	6	0	Killed by winter.
Chautauqua	6	3	Good summer growth.
Red Jacket	6	1	Weak growth.
Smith's Improved	6	6	Vigorous growth.
Houghton	6	1	Healthy summer growth.
Downing	6	2	Weak growth.
Golden Prolific	6	0	Killed by winter.
Columbus	6	2	Fair growth.
Whitesmith	6	4	Very vigorous growth.

Raspberries.

The raspberry canes, although laid down and covered with earth, suffered more from the frost of last winter than any one other season since they were planted.

There is one variety, however, known as Reeder, which was exposed to exactly the same conditions as the other sorts, but has shown greater hardiness and passed through the winter almost uninjured. Out of 21 varieties tested this yielded the most fruit.

The Sarah, Turner and Philadelphia were, next to the Reeder, the least injured by the winter.

Snyder Blackberry fruited this year for the first time. It bore large bunches of fine fruit which ripened very late. This blackberry has wintered here three seasons, but requires some protection.

No new raspberries were planted this season, but many imcomplete rows were filled. This work can be done any time through the early part of the summer after the suckers have started to grow by transplanting the young green shoots.

A dull rainy time is generally chosen for this work. Holes are dug where the plants are required; good thrifty suckers are selected and dug with a sharp clean spade, care being taken that a lump of earth adheres to the roots in each case, and this, without being disturbed, is placed carefully in the holes prepared and firmly pressed.

Prune back slightly, and if the sun becomes very hot, shade for a few days with a shingle.

By this method, the raspberry plantation can be rapidly increased, as most varieties produce suckers freely, and the work can be done at a less busy time than during the spring.

FOREST TREES.

The trees in the shelter belts and plantations continue to thrive, many of the varieties having made very fine specimens. A list of those believed to be suitable for general planting is here continued, which it is hoped will be found useful to intending planters.

Populus Petrowskiana—Russian Poplar.—This is one of the fastest growing varieties of the poplars imported from Northern Europe. It has luxuriant foliage, which hangs late on the tree. A nine year old tree was recently measured here, and found to be twenty feet high, with twelve feet spread of branches. The trunk one foot from the ground was five inches in diameter. This is propagated by cuttings.

Betula alba laciniata—The Cut-leaved Birch.—This is a variety of the White Birch of Europe; and is fairly hardy here. Its symmetrical habit, coupled with its graceful pendulous branches and finely cut leaves, makes it a desirable acquisition. A tree five years planted is ten feet high. This can be propagated only by grafting or budding. As it is somewhat difficult to transplant, much care should be exercised in this operation.

Betula pumila—Dwarf Birch.—This is a dwarf variety indigenous to this conntry. Its maximum height is about ten feet; its form is attractive and its dwarf habit makes it useful for hedge purposes. The seed is ripe in August, but only a small percentage of it is usually found to germinate. Seedlings may be procured from the woods, where it grows in some localities in great profusion.

Alnus viridis—American Alder.—This is also a native tree, with a dwarf habit. The present height of a tree on this farm, eight years old, is nine feet, with a spread of branches of three and a half feet.

Picea pungens—Rocky Mountain Spruce.—Specimens of this tree have now stood six successive winters. To secure the best results this tree should be planted in the shelter of other trees and shrubs, as it is often hurt by the hot dry winds that prevail on the open plains. It is a native of the Rocky Mountains in Colorado.

Larix Europæa—English Larch.—One specimen, the only survivor of a large consignment received in 1890, is doing wonderfully well; it is ten feet high and seems quite hardy. Our native larch (*Larix Americana*), however, is much more successfully grown.

Thuya occidentalis Elwangeriana.—This is a beautiful variety of the western Arbor Vitæ, and has a more finely cut foliage and a very symmetrical form. Specimens have proven hardy here when grown in protected situations.

Cost of Planting and Maintaining Forest Trees.

In the spring of 1895, a plantation of one acre in extent was planted near the main road with two-year-old seedlings of the native Ash-leaved Maple and White Elm. The object in planting this plot was to ascertain the cost of planting and maintaining an acre of trees until they were large enough to shade the ground and prevent the further growth of weeds. After four years this plot has reached that stage, and in future will be kept clean with a few hours' work around the edges. The average height of the trees is eight feet.

Particulars of the cost of planting and taking care of these trees for 4 years are herewith submitted.

Approximate cost of growing and digging trees...........	$ 5 00
Cost of planting, 20 hrs. work..........................	3 00
Filling vacancies, 5 hrs. work..........................	0 75
1st year, cost of cultivation, hoeing, etc, 20 hrs. work	3 00
2nd " " " 15 "	2 25
3rd " " " 10 "	1 50
4th " " " 5 "	0 75
	$16 25

Another experiment of this sort was begun last season by the planting of an acre plot with elm, maple and ash with alternate rows of Sand Cherry. The object of this experiment is to ascertain how quickly the Sand Cherry will shade the ground and save the labour of further cultivation.

This plot has become well established, and the trees are growing rapidly.

Avenues.

Three kinds of trees have been used for avenue planting, and up to the present time about three miles of roads have been improved by planting there double rows of trees.

The native Ash-leaved Maple (*Negundo Aceroides*) has been chiefly used. This well known and deservedly popular tree seems especially adapted for this purpose here, it thrives luxuriantly and is kept in order with a small amount of work.

Avenues have been successfully planted here by selecting trees about four or five years old of good shape ; nursery grown specimens on account of their superior root development are preferred. When the row is planted the trees are pruned to a uniform height and, as far as is practicable, the same uniformity is observed in the height of their lowest branches, as this adds much to the beauty of the avenue. Twenty feet apart is about the right distance to plant this tree. Cultivation is carried on as follows:

When the first crop of weeds have come nicely through the ground, which is about the 1st of June, a space of at least four feet on each side of the row is ploughed with a one horse plough, the ploughing near the tree being very shallow to avoid injuring the roots. This is followed by a good harrowing with one large section of a harrow. Later in the season the ground should be kept clean with a one horse cultivator. Pruning is done each year in July, as at this season wounds in the tree heal rapidly. Any pendulous branches are shortened, and any dead wood found is cut out.

When examining the avenues here this season twenty of the trees were found to be unhealthy. This was attributed to two causes. Six of them were found to be in low undrained locations, and on digging three of these their fibrous roots were found to have rotted, which was probably the cause of death. The soil in these low places was a stiff clay locally known as gumbo. In replanting trees in such places, holes should be made much larger than required for the roots and soil added from the higher land on the farm ; if slightly gravelly, so much the better. This method is also followed when planting trees in alkaline spots.

The remaining trees were found to be badly affected by sun-scald and in some cases the wood had split the whole length of the stem and much of the bark was dead. This may be treated by carefully paring off the dead bark until the hard wood is reached, when the edges of the wound will callous and the wound will often heal.

Native Spruce *Picea alba* is another tree which has been used here to advantage for avenue planting and has made fine growth, in some cases outstripping the maples in height.

Its evergreen foliage makes it a very desirable tree for this purpose.

Another tree which has been used here for avenues is the Russian poplar (*Populus Bereolensis*). This is a fast growing species and is much admired for its symmetrical form. It also has the advantage of retaining its leaves until quite late in the season.

Notes on the Arboretum.

In the spring of 1893, on a rough looking hillside surrounding the then newly built Superintendent's house, the nucleus of an arboretum was started ; a terraced lawn was graded and laid down to sod, and about one hundred trees, of forty varieties planted ; since that time each year new varieties have been added, until at present 1,023 trees of 226 varieties and species are growing. This has changed the aspect of the landscape and given beauty to the surroundings.

In the summer this plot claims much attention from the visiting public, and from the many inquires made and the growing interest manifested in tree growing throughout the province, it is evident that this department of the farm is doing good work.

A catalogue of this plantation has been made, each tree has been numbered and a record made of time of planting, hardiness, etc.

A very substantial enlargement was made this year by the addition of many varieties received from the Central Farm two years ago and placed in a nursery then. They have thus been tested here for two winters; they are not all entirely hardy, but all stand the winter sufficiently well to make good specimens.

Additions to Arboretum.

Name of Variety.	Remarks on hardiness, growth, &c.
Alnus incana	Hardy, fair growth.
" viridis	" strong "
Acer monspessulanum	Half hardy, weak growth.
Alnus imperialis laciniata	Hardy, fair growth.
Amorpha fruticosa	" large growth, flowered.
Ampelopsis variegata	" fair growth.
Berberis ilicifolia	Half hardy, small growth.
" vulgaris purpurea	Hardy, small growth, flowered.
" Thunbergii	" "
Betula pendula Youngii	" fair "
Cornus sanguinea	Half hardy, strong growth.
" sericea	" "
Cytisus purpureus	Hardy where protected, flowered.

Viburnum opulus sterilis	" strong growth, flowered.

Hardy Ornamental Shrubs.

The following are some of the more promising of the ornamental shrubs which have been tested here:

Amorpha fruticosa—Lead tree.—An indigenous species found growing in this vicinity. Its pretty racemes of flowers make it quite ornamental; the yellow anthers against the back ground of its violet petals, gives the whole a pleasing effect. This comes into flower about 20th June, and is followed by small pods, enclosing seeds from which it is readily increased.

Lonicera tatarica elegans—Elegant Bnsh Honey-suckle.—This is less vigourous in its growth than the common Bush Honey-suckle, but it blooms more freely and is thickly covered with light rose-coloured blossoms during the first week in June; these are followed by bright red berries. It is quite hardy and desirable, and may be propagated by layers or cuttings.

Lonicera gracilis—Graceful Honey-suckle.—In this species the flowers are almost white, followed by yellow fruit. It blooms early in June, and may be propagated from cuttings or by layers.

Sambucus Canadensis—Canadian Elder.—Of the many varieties of elder tested here this is the most vigorous and hardy. A three-year old bush is now four feet high with three feet of spread of branches. This is propagated by root division or from cuttings.

Spirœa Douglasii—Douglass Spirœa.—Height two to four feet. In bloom from 15th July to late in the autumn. This makes a pretty ornamental hedge, suitable for a flower garden, and is very pretty when covered by its dense clusters of pink flowers. This may be propagated by division of the root.

Viburnum Lantana—Way-faring Tree.—This is a handsome ornamental shrub with strongly veined lantana-like leaves. Its flowers are white and are succeeded about the third week in July by pretty clusters of purple fruit, which eventually become black.

Viburnum Lentago—Sheep-berry.—This is a native shrub of much merit. Its large shiny leaves and compact habit of growth combined with the abundance of its flowers and fruit gives it a pleasing appearance. This can be obtained by transplanting naturally grown seedlings or can be raised from seed. This, however, rarely germinates the first season.

Clematis ligusticifolia—This species of clematis is found growing wild in some parts of the North-west Territories and is common also in British Columbia. It is very hardy, grows rapidly and forms a useful climber for a verandah. It is a free bloomer and can be grown from cuttings, layers or seed.

Ligustrum Amurense—Amur Privet.—This is a pretty, almost evergreen shrub, which has so far proven hardy here, and will be found useful for borders or low hedges.

Cytisus hirsutus—Hairy Cytisus.—This littly shrub is well worthy of a place in every collection; it flowers freely through July, and will grow readily from seeds, which are freely produced in small hairy pods. It is not entirely hardy and succeeds best when protected in winter by a covering of earth.

Syringa villosa—Rough-leaved Lilac.—This species of lilac is from Northern Asia and like Syringa Josikea will be found very useful in this province; flowering late it thereby escapes the spring frosts, which so often kill the flower buds of the common lilac. It comes into bloom the second week in July; the flowers are light purple, and the foliage is very much admired.

Hedges.

The sample hedges grown here for comparative test purposes are steadily increasing in number. This feature in our work claims much attention from the general public, especially as the utility of hedges as wind-breaks and snow collectors becomes more apparent. Of the hedges planted in the spring of 1897, all survived the winter, with

Seedling Lilac, eight years planted, growing on Experimental Farm at Brandon, Manitoba.

the exception of the Rosemary-leaved Willow (*Salix rosmarinifolia*), this was killed root and branch. This left 34 hedges living last spring; and to these have been added 11 other species and varieties, making a total of 44 different kinds of hedges now living.

Additions to sample hedges in 1898:—

Lonicera Alberti,	Albert Honey-suckle,
Syringa Josikea,	Hungarian Lilac,
Spiræa Douglasii,	Douglas' Spiræa,
Ligustrum Amurense,	Amur Privet,
Celtis occidentalis,	Nettle Tree,
Rosa rugosa,	Japan Rose,
Shepherdia argentea,	Buffalo Berry,
Artemisia Abrotanum,	English Old Man,
Caragana grandiflora,	Large-flowered Pea Tree,
Lonicera tatarica splendens,	Splendid Honey-suckle.

Distribution of Tree Cuttings.

In accordance with instructions received from the Director last spring, twenty-five thousand cuttings of Cottonwood, Russian Poplar and Willows were prepared and mailed to applicants. Although instructions for this work were received rather late in the season for the best results, we were able to supply all applicants with a package containing 100 cuttings, which was generally made up as follows: 25 Cottonwood, 25 Russian Poplar, 25 Sharp-leaved Willow and 25 Voronesh Willow.

From reports received we learn that very few of the Willows failed, a number of the Russian Poplars struck, but poor success was had with the Cottonwoods, the spring evidently being too dry to permit of the rooting of the wood of this moisture-loving tree.

On this farm Cottonwood cuttings made and planted deeply in fallowed land as soon as the ground is thawed out in the spring, have generally rooted well, but when cut late in the spring, or planted on spring ploughed stubble, they have nearly always failed.

The total number of applicants supplied with tree seedlings and cuttings during the year was 1,237, which is 331 more than last year.

THE VEGETABLE GARDEN.

The season of 1898 was, in many respects a peculiar one for vegetables. Spring was ushered in by a long continued spell of dry weather, and, beyond a slight shower or two, no rain whatever fell until the 25th of May. To aggravate the conditions caused by the drought, high winds were experienced, and the combination of the two evils, caused us at one time to contemplate the entire re-sowing of the vegetable garden. The merits of fairly deep and thick sowing was admirably illustrated in this connection; for, although some of the seed was certainly blown out, the rows were all well filled on the approach of more favourable weather. On the 5th and 6th of June, we received a good soaking, and the balance of the season was all that could be desired, as regards rainfall. The cool weather in the fall interfered considerably with the maturing of some of the late vegetables, and for the first time for some years past, we failed to harvest a crop of ripe tomatoes. This may be accounted for by the fact, that, about the time the first blossoms were setting fruit, we had, a very heavy rain, which appeared to greatly interfere with fertilization, and, as we generally depend on the first flowers for ripe fruit, the failure may be fairly attributed to the above cause. Onions were also thrown back by the very dry condition of the soil in early spring, and did not germinate until quite late, causing the late maturing of this useful crop. With the above exceptions, the yield and quality of vegetables was all that could be desired. All root crops, with the exception of carrots, gave unusually heavy returns, and cucumbers, squashes and pumkins were far above the average. Taken on the whole, the season may safely be termed a favourable one for vegetables. In the experiments with vegetables here the effort has been made to thoroughly test two or three different kinds, procuring as many varieties of each as possible. Those to which special attention was given during the past season, were

beets, cabbage, and cucumbers, and following will be found the results of these tests, together with other portions of the work done in this department.

Cabbage.

The method adopted this season for raising cabbage plants, was one which we have found by experiment to give the best results with a minimum of labour. The seed was sown thinly in a spent hotbed on 19th April, in rows six inches apart, and as soon as the plants were large enough to handle, they were thinned, this operation taking place on 30th April. It is of the utmost importance that thinning should be performed before the seedlings are too tall, a day or two's delay at this time making the difference between dwarf, strong plants and thin straggling ones. From this time air was given whenever the weather permitted, and on 30th May a frame of sturdy and healthy plants were transferred to the open, in rows three feet apart, and two and one-half feet apart in the row. By adopting this p'an, all the labour of transplanting from seed boxes was rendered unnecessary, and the result was fully equal to that previously attained by the mode of twice transplanting. Forty-one varieties were sown, four of which did not germinate, viz.: Quintal Drumhead, Stonemason, Extra Early Etampes and Early Oxheart. The wet fall season proved exceptionally favourable for this crop, and the average was above the ordinary, with the exception of the red varieties, which, for some reason, have not proven satisfactory for some years past. Following will be found the result of this test, together with a list of the most suitable varieties :—

Name of Variety.	Average Weight.	Firmness.	Percentage Headed out.	Early or Late.	Shape.
Savoy Drumhead	7 pounds.	Fairly firm	70 per cent.	Late	Flat.
Hollander	14½ "	Very "	100 "	"	Rounded.
Autumn Giant	14½ "	Firm	73 "	"	"
Early Brunswick	11½ "	Very firm	100 "	2nd early	Flat.
Large Late Drumhead	12 "	Firm	85 "	Late	Rounded.
Early Large York	8½ "	Fair	94 "	Early	Pointed.
Tottler's Brunswick	10 "	Very firm	90 "	2nd early	Flat.
Early Favorite	4½ "	Soft	85 "	Early	Rounded.
Quintal Drumhead (did not germinate)					
Early Dwarf York	7 "	Fairly firm	75 "	"	"
Vandergaw	13 "	Very "	100 "	Late	Flat.
Stonemason (did not germinate)					
Victoria Savoy	8 "	Fairly firm	98 "	"	Rounded.
Early Sugar Loaf	8 "	"	100 "	Early	Conical.
Early Winningstadt	7½ "	Very firm	100 "	2nd early	Pointed.
Red Drumhead	8 "	"	58 "	Late	Rounded.
Extra Early Etampes (did not germinate)					
Chester King	7½ "	Fairly firm	100 "	Very late	Flat.
Succession	13 "	Very firm	100 "	2nd early	Rounded.
Pearce's 2nd Crop	14½ "	"	100 "	"	Flat.
American Savoy	8 "	"	97 "	Late	"
Premium Flat Dutch	23 "	"	93 "	"	"
Early Oxheart (did not germinate)					
The Lupton	19½ "	"	100 "	"	"
All Season	14½ "	"	100 "	2nd early	Rounded.
Early Summer	12½ "	"	100 "	Early	Flat.
Early Jersey Wakefield	9 "	Firm	92 "	"	Conical.
Surehead	17 "	"	97 "	Late	Rounded.
New Extra Early Express	6 "	"	96 "	Early	"
Filderkraut	8 "	Very firm	100 "	2nd early	Pointed.
Deep Head	13½ "	"	78 "	Late	Rounded.
Danish Ball Head	16 "	"	100 "	"	"
Globe Savoy	8½ "	Soft	83 "	"	"
St. Denis	10 "	Very firm	100 "	2nd early	Flat.
Chester Savoy	12½ "	Firm	97 "	Late	"
Luxembourg	8 "	"	96 "	Very late	Rounded.
Matchless Flat Dutch	15 "	"	83 "	Late	Flat.
Burpee's All Head	16½ "	Very firm	100 "	2nd early	"
Marble Head Mammoth	20 "	"	100 "	Late	"
Dark Red Early Dutch	6 "	Firm	64 "	"	Rounded.
Dwarf Ulm Savoy	3 "	Very soft	46 "	2nd early	"

Desirable Early Sorts.—1. Early Jersey Wakefield; 2. Early Sugar Loaf.

Second Early or Summer.—1. Early Brunswick; 2. Filderkraut.

Late or Winter.—1. The Lupton; 2. Marblehead Mammoth.

The following varieties have not succeeded well and are not recommended for cultivation in this province:

1. Autumn Giant; 2. Globe Savoy; 3. Luxembourg; Dwarf Ulm Savoy.

Beets.

Sixteen varieties of beets were sown outside, with hand drill, on 14th May, in rows two feet apart, and all germinated well. In previous years the chief difficulty to be contended with, in connection with this crop was the tendency of the roots to grow too large for table use. This season, by leaving the plants somewhat thicker in the row and sowing the rows closer together, this difficulty was overcome, and the roots were all that could be desired for table purposes. A point deserving special mention, was the superiority of the long varieties over the round or turnip shaped, both in colour and texture. Although at present there seems to be some prejudice against the long beets, it is believed that, if they were more generally cultivated better appreciation would soon follow. On account of the earliness of the turnip-rooted varieties, a few of these should always be grown for early use. Another point observed in connection with this test, was the extremely poor quality of some of the varieties tried, a few being totally devoid of colour, and conspicuous among the latter class were those named The Lentz, Bassano Flat Red, and Eclipse. In the following table the varieties tested are arranged in the order of their productiveness.

Name of Variety.	Colour.	Shape.	Yield per Acre.
			Bush.
The Lentz	Poor, contains white rings	Turnip	1,358
Simmer's Extra Early	Very dark	Flat	847
Early Blood Turnip	Fair, contains white	Turnip	847
Eclipse	Very white	"	847
Whyte's Very Long Blood Red	Very dark	Long	836
Early Flat Red Bassano	White	Flat	814
Early Dark Red Egyptian	Very dark	"	792
Arlington Favourite Blood	"	"	715
Columbia	Fair, contains white	Turnip	715
Edmond's Blood Turnip	Dark	"	704
Dewar's Half-long Blood	Bright red	Half-long	660
Long Smooth Deep Blood	Very dark	Long	660
Extra Long Smooth Blood Red	"	"	616
Black Prince	"	Turnip	605
Olive Shaped Black Red	"	Olive shaped	440
Black Queen	"	"	383

The following are specially recommended as among the best:

1. *Simmer's Extra Early* (Turnip-shaped);
2. *Early Dark Red Egyptian* (Turnip-shaped);
3. *Dewar's Half Long Blood* (Half long);
4. *Long Smooth Deep Blood Red* (Long).

Cucumbers.

Cucumbers were an unqualified success this season, the yield and quality being fully up to if not above the average.

Twenty-five varieties were sown on 23rd May in hills 6 feet apart each way, and as soon as practicable the plants were thinned and reduced to three per hill. Until the vines commenced to spread, the soil was occasionally stirred with the horse cultivator, this being all the labour necessary. The method of sowing was as follows: One man with a hoe taking the lead made the holes at regular intervals; another followed dropping a small quantity of seed into the excavation, and with his foot drawing the soil together and pressing it firmly upon the seed. In this manner the work is performed rapidly, and has always been attended with excellent results. A feature to be regretted in connection with this crop was the astonishing mixture of varieties, some of them, especially the Japanese Climbing, producing three or four distinct types of fruit, making it difficult to select the typical variety. One of the earliest and most prolific varieties was Early Russian, a cucumber which should prove exceptionally valuable to market gardeners, on account of its ability to withstand constant pulling, the fruit forming very rapidly.

Giant Pera was the largest variety tested, and produced some magnificent fruit, perfectly straight, smooth and uniform of a beautiful light green colour, and possessing a fine flavour. The variety listed as Serpent proved to be merely a curiosity, and was entirely worthless for the table, although showing some most fantastic forms. The results of this test are below arranged according to earliness.

Name of Variety.	Ready.	Average Length.	Diameter.	Shape.	Flavour.	Average Weight.	Productiveness.
		in.	in.			oz.	
Russian Gherkin......	Aug. 15	....	....	Similar to Early	Russian.

Potatoes—Test of Various Divisions of.

Size of Division.	Percentage of Germination.	Weight Planted.	Weight of Large Harvested.	Weight of Small Harvested.	Total Weight.	Form of Tubers.
	p. c.	Ozs.	Lbs.	Lbs.	Lbs.	
Large, whole	100	$26\frac{2}{5}$	9	$3\frac{1}{2}$	$12\frac{1}{2}$	Irregular.
Whole, minus ends	100	16	8	$3\frac{1}{4}$	$11\frac{1}{4}$	Fairly regular.
Whole, small	100	$7\frac{1}{5}$	10	$1\frac{3}{4}$	$11\frac{3}{4}$	Very good sample.
Seed ends only	$96\frac{8}{27}$	$1\frac{5}{16}$	6	$\frac{3}{4}$	$6\frac{3}{4}$	Fairly regular.
Two eyes together	$73\frac{1}{3}$	$3\frac{7}{15}$	6	$\frac{3}{4}$	$6\frac{3}{4}$	Regular.
Three "	$89\frac{19}{29}$	$4\frac{28}{29}$	7	$\frac{1}{2}$	$7\frac{1}{2}$	Good sample.
Four "	$86\frac{2}{3}$	$6\frac{3}{5}$	7	$\frac{1}{4}$	$7\frac{1}{4}$	Irregular.
One eye separate	36	$1\frac{1}{5}$	$16\frac{1}{2}$	1	$17\frac{1}{2}$	"
Two eyes "	10	4	9	1	10	Fairly regular.
Three "	$23\frac{1}{3}$	$5\frac{1}{5}$	$7\frac{1}{2}$	$\frac{3}{4}$	$8\frac{1}{4}$	"
Four "	$23\frac{1}{3}$	$6\frac{2}{5}$	$13\frac{1}{2}$	1	$14\frac{1}{2}$	Irregular.

In the foregoing table the low percentage of germination in the small divisions show that these would not be as reliable during a dry season, the greater portion of them dying from dry rot, a fact proven by examination. On the other hand, the small sets which came to maturity, show by their comparatively heavy returns, that, in a moist season, they would probably have headed the list.

The Large whole potatoes, did not give a corresponding yield to the weight of tubers planted, and the result points to the inadvisability of planting very large sets. Small whole potatoes were more satisfactory, and give promise of furnishing in a favourable season means of disposing of some unmarketable potatoes. The result from seed ends only shows the error of a prevalent theory held in this vicinity, as to their worthlessness for seed purposes. Though the returns from these are not high, the fairly regular appearance of the product clearly shows that this portion may be used to advantage.

Onions.

The most important point brought out in the onion tests, was the superiority of the transplanted product over that from outside sowing. The manner in which this work was done here was as follows : The seed was sown in boxes in a hot-bed on 7th April, and on 20th April, was transplanted into boxes, setting the plants about one inch apart each way. After a gradual hardening off, they were transferred to the open ground on 13th May, a small dibler being used for this purpose. A thorough watering at this time completed the operation, although the yield is increased by this method, it is doubtful if it would pay growers to adopt this plan generally, on account of the somewhat low prices obtained for the crop. The yield of onions on the whole, was below the average, and they were later in maturing on account of the exceptionally dry spring.

Extra Early Red was the earliest variety, and Adriatic White Barletta proved to be a first class pickler, producing about 60 per cent of small uniform bulbs. The following results were obtained.

Onions sown outside in rows 14 inches apart on 11th April.

Name of Variety.	Pulled.	Ripened.	Colour.	Shape.	Yield per Acre.
	1898.	1898.			Bush.
Extra Early Red	Sept. 20	Sept. 26	Red	Flat	$339\frac{25}{60}$
Yellow Danvers	" 20	Oct. 5	Yellow	Globular	$320\frac{13}{60}$
Adriatic White Barletta	" 20	Sept. 20	White	Pickling	$153\frac{17}{60}$

Onions sown in hot-bed 7th April, transplanted into boxes 20th April, and planted outside 13th May.

Name of Variety.	Pulled.	Ripened.	Colour.	Shape.	Yield per Acre.
	1898.	1898.			Bush.
Exra Early Red	Sept. 15	Sept. 20	Red	Flat	390
Yellow Danvers	" 15	" 20	Yellow	Globular	$365\frac{18}{60}$

Pease.

The first five varieties in the following list, form a suitable succession of varieties for this province. Gradus and Prosperity are peas which are said to be earlier and better in quality than American Wonder. As tested here these two sorts seem to be identical.

The quality is certainly ahead of the American Wonder, but this advantage is offset by their lack of productiveness, and the fact of their being much later than American Wonder. All were sown in double rows, with hand-drill on 2nd May.

Name of Variety.	Ready.	Length of Pod.	Length of Vine.	No. of Peas in Pod.	Ratio of Productiveness.	Seed.
Alaska	July 10	2 inches.	14 inches.	4-5	5	Ripened.
Nott's Excelsior	" 8	2½ "	8 "	5-6	10	"
Horsford's Market Garden	" 18	4 "	24 "	8-9	10	"
*American Wonder						
Shropshire Hero	July 30	4 inches.	18 inches.	7-8	10	Ripened.
Gradus	" 18	4 "	18 "	5-6	5	"
Prosperity	" 18	4 "	18 "	5-6	5	"

* Similar to Nott's Excelsior.

BEANS.

Four varieties were sown on 21st May, in rows 2½ feet apart, and the result of the test is given below.

Name of Variety.	Ready.	Length of Pod.	No. of Beans.	Productiveness.	Seed.
Giant Dwarf Wax	August 15	6¼ inches.	4 inches.	Very.	Ripened.
Wardwell's Kidney Wax	" 20	7 "	5 "	Fairly	"
Golden Wax	" 15	6 "	4 "	Very.	"
Flageolet Scarlet Wax	" 23	7 "	5 "	"	"

CORN.

As will be seen from the following tabulated result, Cory corn from seed ripened here last season, was ready for use a few days earlier than from the imported seed. Attention is also called to the Improved Squaw Corn, as being a valuable variety for Manitoba. Sown on 21st May in rows 3 feet apart.

Name of Variety.	Ready.	Variety.	Length of Ear.	Flavour.	Seed.
			Inches.		
Cory (Own Seed, 1897)	Aug. 23	Dent	6½	Good	Partially ripened.
" imported	" 27	"	6½	"	"
Improved Squaw	" 18	Flint	7½	Fair	Ripened.

RADISH.

Two varieties of radish were sown on 25th April, viz.: Scarlet Olive Shaped and Brightest Long Scarlet, and were ready for use respectively on 3rd and 5th June. The unusual long period intervening between these dates, was occasioned by the very dry spring, which prevented prompt germination. Both were excellent varieties.

PARSNIPS.

The yield of parsnips was considerably above the average this season. The only variety tested was the Hollow Crown.

TOMATOES.

Three varieties of tomatoes were tested, and, none produced ripe fruit. The reasons assigned for this were, the imperfect fertilization of the early blossoms, coupled with the cool fall weather.

SQUASH.

We were favoured with an abundant crop of this vegetable, the yield and quality being exceptionally high. The variety known as Extra Early Orange Marrow deserves special mention as useful for Manitoba. It is very prolific, ripens early, and can be used either as a vegetable or for pies, making a pie quite equal to the pumpkin. This makes it very desirable, as the average season will not produce ripe pumpkins here except in very limited quantity. The outer color of this squash is a deep orange, and the flesh a clear lemon yellow. The bush varieties of squash have again shown their value in this próvince, and their superiority over most of the running forms.

LETTUCE.

Two varieties of lettuce were sown. Toronto Gem and Self Folding Cos on 11th April. On account of the dry spring, they were very late in arriving at maturity. A test has been made of fall sowing this season, and in this way we hope to have early lettuce next spring.

CAULIFLOWER.

Early Snowball, Large Erfurt and Autumn Giant, were the three varieties tested this season, and as in previous years, the first named was by far the best variety. Autumn Giant is too late for this vicinity, the heads not forming before frost.

CARROTS.

Carrots were only a fair crop this season, occasioned, principally, by delayed germination caused by the dry spring weather. Chantenay, Peer of All and Coreless, were the varieties tested. Chantenay headed the list, in shape flavour and yield.

TURNIPS.

Two varieties of garden turnips were sown, viz. : Extra Early Milan and Hazard's Swede. There was evidently an error in the name of the latter, as there was no similitude between Hazard's Swede as previously grown here, and that grown this season. Both were early garden strap-leaved turnips, and did not remain palatable for any length of time.

TOBACCO.

The variety grown this year was Connecticut Seed Leaf, and being a fairly early kind, it was hoped that ripened leaves would be harvested. The coolness of the season, however, prevented this, and the plants were frozen whilst in a green stage.

ASPARAGUS.

Asparagus continues to give satisfaction. All varieties under cultivation, are in good condition, and improving yearly. This vegetable requires very little attention, and is a strong and free grower and one of the most acceptable delicacies of its season for the table.

MUSK MELON.

Three varieties of melons were tested: Yellow Cantaloupe, Banquet and McCotter's Pride. None produced ripe fruit, Yellow Cantaloupe approaching nearest to ripeness.

CELERY.

Four varieties of celery were tested this season, viz.: White Plume, Imperial, Giant Pascal and London Prize Red, and all grew well. Hilling was accomplished by using drain tiles, no soil being thrown up whatever. The product was well blanched, and of excellent flavour and more crisp than any previously grown here by the soil-hilling process. Celery growers would do well to give this method a trial.

THE FLOWER GARDEN.

The flower garden during the past season was an unqualified success, and the profusion of bloom during the summer months, attracted much attention from visitors. The mixed border was especially admired, the combination of the various colours of annuals and perennials forming a very pleasing picture. One of the most noticeable of the new varieties of annuals tested was *Chrysanthemum inodorum plenissimum*, a very free blooming double white variety, and hardy enough to continue in bloom for a considerable time after frost. It possesses a special value as a cut flower, on account of its long slender stems, and keeping qualities.

Asters, we regret to say, were again a decided failure, and produced about 90 per cent of deformed blossoms. Unless a remedy for this disease is found it may be better to discontinue the cultivation of this hitherto most valuable annual. The herbaceous perennials made a good showing, and attention is called to some of the more recent introductions at this farm on a later page.

Following is a list of the annuals tested. They were sown in boxes in hot-bed on 11th April, transplanted 18th to 25th April, and planted outside 7th to 14th June.

Name of Variety.	Flowering Period.
Asters (7 types)	July 15 to frost.
Phlox Drummondii	June 15 "
Verbena auriculæflora	" 18 "
Salpiglossis variabilis	" 30 "
Zinnia elegans	" 15 "
Antirrhinum Queen of North	" 25 "
" Half High	" 25 "
" Tom Thumb	" 25 "
Stocks (3 types)	" 14 "
Petunia, Double	" 25 "
" Single	" 15 "
Gaillardia grandiflora Hybrida	Aug. 12 "
" *picta*	June 25 "
" *Lorenziana*	" 25 "
Chrysanthemum inodorum plenissimum	" 20 "
Nigella damascena alba	" 20 "
Acrolinium roseum	" 7 "
Datura Henherriana	July 20 "
Brachycome iberidifolia	June 15 "

The following annuals were sown outside on 26th May, 1898, and not transplanted.

Name of Variety.	Flowering Period.
Poppies Peony flowered	June 20 to frost.
" The Shirley	" 20 "
Mignonette mixed	" 25 "
Nasturtium Dwarf	July 5 "
Portulaca mixed	" 20 "
Linum roseum	June 30 "
Godetia mixed	July 5 "
Calliopsis mixed	June 30 "
Sunflower Dwarf	" 25 "
Sweet Peas mixed	July 15 "

Herbaceous Perennials.

On page 352 of last year's report, a list of perennials was given, which had withstood one winter only, and whose hardiness could not be positively stated. Following is a list of those varieties which have withstood the winter of 1896-97, and may perhaps be accounted hardy for this province.

1. Lychnis Haageana Hybrids.
2. Hemerocallis flava.
3. Hesperis matronalis.
4. Polemonium reptans.
5. Baptisia australis.
6. Orobus lathyroides.
7. Gypsophila paniculata.
8. Asclepias tuberosa.
9. Stenactis speciosa.
10. Alyssum argenteum.
11. Lychnis Chalcedonica alba.

The varieties mentioned on page 352 of last year's report, some of which date back from 1893, are alive with one exception, viz.: *Anthemis coronaria*, which died during the past winter.

Of the roses mentioned on page 353 of last year's report, the following are alive at this date (November, 1898):

1. Baron Prevost, flowered 1898.
2. Mad. Plantier, did not flower.
3. Gem of Prairies, do
4. From A. P. Stevenson, Nelson, flowered 1898.

All of the above have made excellent growth during the past season, and are in good condition for winter.

Hyacinths.

The hyacinths mentioned in last year's report as having survived the winter of 1896 by heavy covering, came through last winter with the aid of an ordinary manure mulch.

Collection of Herbaceous Perennials.

This collection has been added to considerally, and now comprises a large number of species and varieties. A number of native perennials, which were located during the summer, have been lifted this fall, and will be planted in the spring.

Iris Hispanica.

This beautiful iris has, in all previous tests, succumbed to the severity of our winters. Last fall, one bulb each of 10 varieties, was planted, and protected in a simi-

lar manner to the Hyacinths, tar-paper, and a very heavy covering of manure being given. All came up in the spring and flowered well thus showing that by heavy covering, these bulbs may be successfully cultivated in Manitoba.

Twenty-five varieties of *Japanese Iris* (*Iris Kœmperi*), and 14 varieties of *Japanese Peonies*, were received from the Central Farm in the fall of 1897, and planted in the collection of Perennials. All came through alive last spring, and some of the Irises flowered, making a valuable acquisition to the stock of Perennials.

The following plants were received from the Central Farm on July 25th, 1898. As fall planting has proven unsatisfactory, these were put into a cold frame on arrival, and will be transferred to permanent location in the spring.

Iris amoena Verschur.	*Campanula Carpatica.*
" *plicata Gisele.*	*Ajuga genevensis.*
" *squalens Tristesse.*	*Achillea ptarmica fl Pl.*
" *neglecta Salvatori.*	*Lysymachia Clethrifolia.*
" *squalens Tarquin.*	*Epimedium rubrum.*
" *variegata Coquette.*	*Spiraea venusta.*
" *plicata Lord Seymour.*	" *ulmaria.*
" *Florentina.*	*Rudbeckia laciniata.*
" *variegata Henry Havard.*	*Hemerocallis graminaefolia.*
" " *Souvenir.*	" *Kwanso fl. Pl.*
Polemonium reptans.	" *disticha.*
Doronicum plantagineum excelsum.	" *Dumortieri.*
Achillea millefolium rubrum.	" *fulva.*
Phlox subulata Newry Seedling.	" *Thunbergii.*
" *decussata Dwarf white.*	

LILIES.

The following lilies were received from the Central Farm in 1897, and planted in the collection of Herbaceous Perennials. All came through the winter, and two flowered. This is a valuable addition to the list of perennials here, no special covering was used for protection.

Lilium davuricum Sappho.	*Lillium Kamschatkensis.*
" *elegans transiens.*	" *elegans fulgens Batemani.*
" *callosum.*	" *Concolor.*
" *Leichtlinii*	" *Krameri.*
" *Hansoni.*	

Ninety-three varieties of Perennial Flower seeds were received from the Central Farm at Ottawa during the winter of 1897. These were sown in seed beds in the spring of 1898, and 38 varieties germinated. As these seeds were gathered from plants growing at the Central Farm, it may be presumed that the low germinating power was caused by their not being fully ripened.

DISTRIBUTION OF SEED GRAIN, POTATOES, &c.

The distribution of both three-pound samples and larger lots of grain has increased this year, and many favourable reports have been received from parties supplied.

The following quantities were sent out to applicants :—

Wheat, two bushels or more	16
Oats " "	7
Barley " "	37
Grain of all kinds in three-pound bags	361

DISTRIBUTION OF POTATOES, &c.

Potatoes in three-pound bags	129
Maple seed, one pound "	165
Flower seed, packages	121
Rhubarb roots, "	71
Vegetable seed, "	46
Perennial flowering plants, packages	79
Trees and cuttings, packages	1,237

NEW BREAKING.

The thirty-seven acres of new breaking mentioned on page 354 of last year's report gave a very satisfactory crop, a portion of it yielding sixty-three bushels of barley per acre; evidently disc-harrowing of tough sod after backsetting is a benefit.

During the past summer thirty-five additional acres have been broken and backset; thirteen acres of this was an old pasture field of native sod where the grass was nearly run out. It is proposed to use this field for grain for two or three years, and then seed it down again to grass.

BUILDINGS.

No new buildings have been erected during the past year, but the barn and driving shed have been repainted, and transom windows placed over the doors of the cattle and horse barn. This latter improvement provides for much better ventilation.

BARN-YARD MANURE.

Many farmers complain of inability to properly rot barn-yard manure in this country. Several hundred loads of excellent manure is made on this farm each year, and successfully rotted by the following method:—

The long, strawy manure, fresh from the stable, is drawn into a depression situated a short distance from the barn, and spread in layers about a foot thick, care being taken that the pile is commenced early in the fall, so as to start fermentation before very cold weather sets in. As the snow drifts on manure it is melted by the heat produced from the fermentation, and this aided by the rains of summer thoroughly saturate the pile, and in the following fall the manure is so well rotted that it can be cut with a spade; whereas if left in a conical pile above the surface of the ground in the dry seasons, which prevail here, it will often dry out and fail to ferment.

Experiments have been tried here with fresh manure, drawing it directly from the barns to the field, but so far this plan has proved a failure, the manure dries up and fails to rot, and is in that shape difficult to plough under.

Better success has been had with such manure when cut straw has been used for bedding, but it was found that more straw was required when this plan was adopted, and that it entailed a great deal of extra labour.

FARMERS' MEETINGS.

Work in this connection has increased very much of late years, and as many meetings are attended as is practicable with the limited time at my disposal. It is not possible to accept nearly all the invitations received to speak at farmers' gatherings.

Since my last report twenty-five meetings have been attended, many of the places mentioned in the following list were visited in succession during the one trip, thus saving both time and money. The average attendance was larger than usual this year.

Jan. 31, Bird's Hill,
Feb. 1, Kildonan,
" 2, Morris,
" 3, St. Jean Baptiste,
" 4, Manitou,
" 5, Nelson,

CORRESPONDENCE.

The correspondence of this office again shows an increase. This year 4,670 letters were received, and 3,584 dispatched, irrespective of 1,804 circulars sent out.

I have the honour to remain, sir,
Your obedient servant,

S. A. BEDFORD,
Superintendent.

EXPERIMENTAL FARM

FOR THE

NORTH-WEST TERRITORIES

REPORT OF A. MACKAY, SUPERINTENDENT.

EXPERIMENTAL FARM, INDIAN HEAD, N.W.T.,
30th November, 1898.

To WM. SAUNDERS, Esq.,
Director Dominion Experimental Farms,
Ottawa.

SIR,—I have the honour to submit herewith to you the eleventh annual report of the operations on the Experimental Farm for the North-west Territories at Indian Head, Assiniboia, during the year 1898.

The past season has been one of bright promises and fair fulfilment. Last winter, like that of 1896-7, was fine; snow was abundant and cold not excessive. The spring, however, was backward and a cold snap following a heavy fall of snow in the latter part of March and first week of April was the cause of considerable loss to stockmen throughout the Territories.

Spring opened about the middle of April and the weather continued fine until seeding was completed.

Some districts had sufficient moisture to cause early and even germination of the seed: others, however, were lacking in this respect but rains later on made up the deficiency in time to ensure a fair and in many cases a good crop.

Winds, though by no means entirely absent, were not very troublesome during the growing season and the loss from this source was small in comparison with that of previous years.

Rains, during the months of May and June, were sufficient to cause satisfactory growth, except in a few districts where the rainfall was below the average, but the heavy downpour necessary to rush the growth was absent until about the middle of July. The grain received a set-back during this month by a week of excessively hot weather but was saved from serious injury by subsequent heavy rains. In addition to the excessive heat and heavy rains in the month of July, there were several drops in the temperature which came dangerously near the freezing point and in some instances caused the grain to be blighted.

Harvest, however, came early with a promise of exceptionally good yields in nearly every district throughout the Territories. The harvest was a tedious one on account of the heavy and continuous rainfall, and it is safe to say that in no previous year in the grain growing history of the country has there been witnessed such a long period of rain and unfavourable weather during the usually fine months of September and October.

Never before has the land been so wet in the fall and in no previous year have the farmers been at so much trouble and expense in securing their crops. While all found it a tedious and expensive undertaking, many rushed the stacking and where this part of the work was well done were safe; others, however, risked threshing from the stook and have paid the penalty in delayed threshing and lower grades, if not seriously damaged grain.

Weeds, especially lamb's quarters (*Chenopodium album*) were more numerous than ever and in many cases were the cause of considerable loss to grain-growers. The more dangerous varieties such as Stink Weed (*Thlaspi arvense*), Tumbling Mustard (*Sisymbrium altissimum*) and Hare's Ear Mustard (*Conringia orientalis*) are extending in all directions. It is, however, gratifying to note the increased amount of attention they are receiving at the hands of individual farmers, Municipal Councils and the North-west Government.

The crops on the Experimental Farm have, with the exception of the hay crop, been very satisfactory. Wheat, oats, barley and pease gave excellent yields. The samples of some varieties of wheat and oats are not equal to those of last year while others are better. Roots and vegetables, especially potatoes, gave good yields and were of excellent quality.

The exceedingly dry fall of 1897 and an insufficiency of moisture early this spring combined to cause a light crop of hay. This fall, however, a good crop of pasture has been produced by the heavy rains, and with the present wet condition of the ground a good crop of hay is looked for next year.

Fruits of both wild and cultivated varieties were a poor crop. Frost in May ruined the blossoms of everything except red and white currants, raspberries and gooseberries. Native fruits were very scarce in many localities, while in others raspberries were an abundant crop.

Needless to say, with the overabundance of rain, trees made a most vigorous growth. Whether the growth has been too vigorous or has extended too late in the season, cannot be determined till next spring. It is probable, however, that such has been the case and that many varieties of trees will suffer greatly through the action of frost on the imperfectly matured wood.

Cattle throughout the Territories have done exceedingly well the past season. While many came through last winter very thin, the abundance of pasture during the grazing season has put all in good condition. Flies were less troublesome than usual. Good prices have been obtained for export beef and on local markets.

EXPERIMENTS WITH SPRING WHEAT.

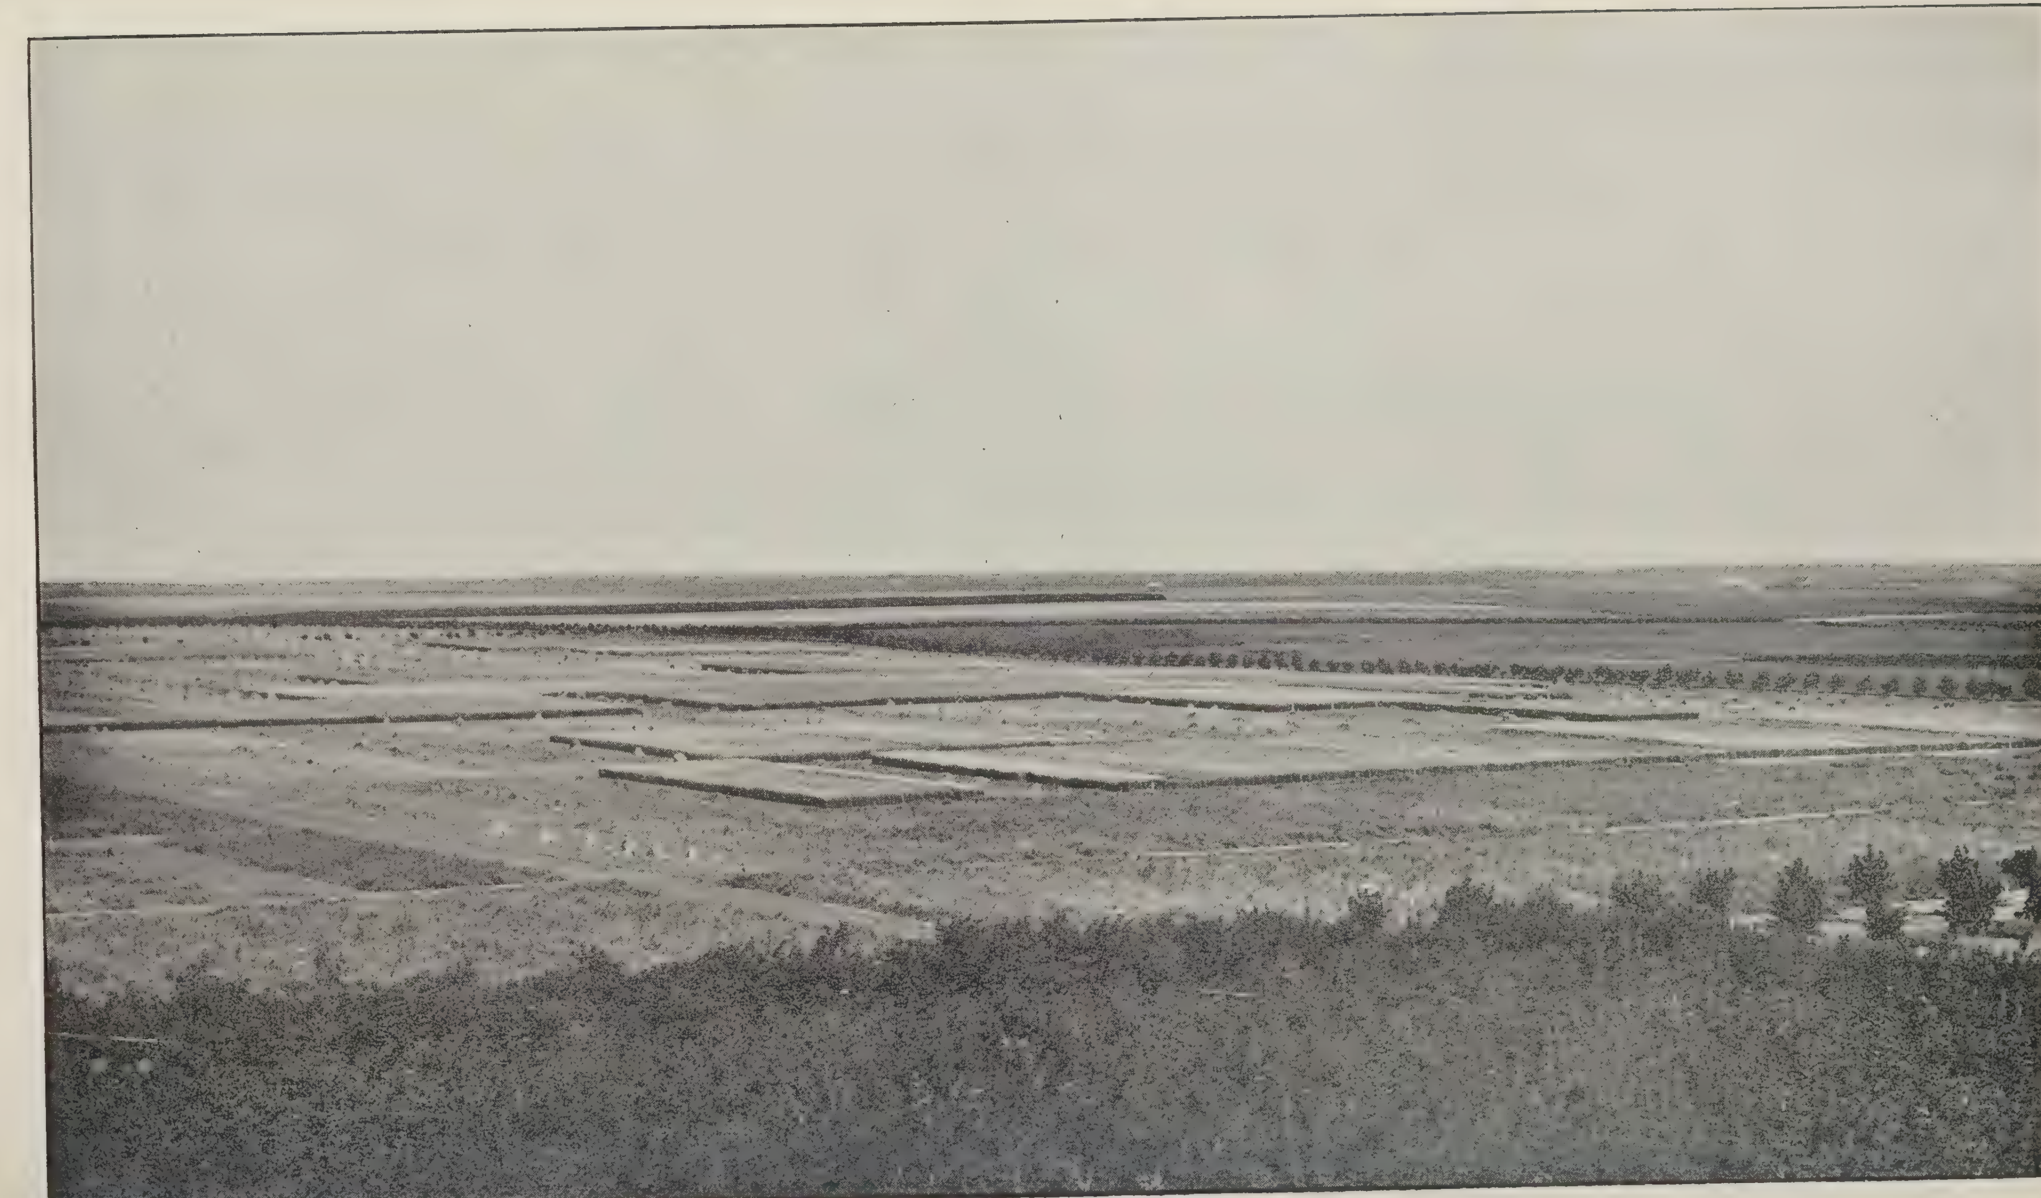
Forty-two varieties of wheat were tested in $\frac{1}{10}$th acre plots, eight of the same varieties again on plots of one acre each, and six varieties on fields of from two to six acres.

RESULTS OF EARLY, MEDIUM AND LATE SOWINGS.

Red Fife and Stanley were used in this test. The soil was clay loam. The land had been fallowed in 1897 and was in good condition when sown. The seed was sown by hoe-drill, at rate of one and one-half bushels per acre. The first plots were sown on 16th April and six successive sowings were made one week apart, the last plots being sown on 21st May. All seedings came up evenly and ripened and were harvested in the order sown.

The first three seedings of both varieties gave the highest yield and were much superior in quality to the later plots. The result of the test is practically the same as in 1896 and 1897.

The crops from the last two seedings of Red Fife and the last seeding of Stanley were quite green when frost came on 8th September, and although the yield was not affected, the sample was more or less damaged. There was no rust on any of these plots.



General view of Experimental Farm at Indian Head, N.W.T., showing Experimental Plots and Fields of grain.

WHEAT—TEST OF VARIETIES ON FIELDS OF ONE TO SIX ACRES.

As heretofore, in these tests the more promising varieties of wheat grown in previous years were sown in field lots, not only to test the grain on larger areas, but for the purpose of obtaining seed in quantities for distribution of samples and for sale for seed.

The plot of Hungarian wheat was in a low portion of the field, and suffered in yield and sample from a cold wave in August.

The soil was clay loam; the seeding was done by hoe-drill at the rate of one and one-half bushels per acre in all cases. The 8 acres of Red Fife was on summer-fallowed land; the 4 acres was sown after roots, and the 1¾ acres on Brome grass sod broken and back-set.

SPRING WHEAT—TEST OF VARIETIES IN UNIFORM PLOTS.

Forty-two varieties were sown on April 21 on $\frac{1}{10}$th acre plots of summer-fallowed land, by hoe-drill, 3 inches deep, and at the rate of one and one-half bushels of seed per acre. The soil was clay loam. The crop of straw was not excessive on any of the plots, and the yield of grain was rather better than last year. Some of the samples, however, were not so good, caused, no doubt, by the hot weather in July. There was no rust on any of these varieties.

BLUESTONE AS A REMEDY FOR SMUT IN SPRING WHEAT.

In this test ordinary clean Red Fife seed and very smutty seed were used. The smutty seed was the product of very smutty seed sown without treatment the year previous, and was unfit for any purpose whatever.

Variety of Seed.	Condition of Seed.	Treatment.	Yield per Acre.		On 25 Sq. Feet.	
					Good Heads.	Smutty Heads.
Red Fife	Clean seed	Bluestoned, 1 lb. to 10 lbs	35	40	1,123	0
"	"	Untreated	35	..	1,126	12
"	Smutty seed	Bluestoned, 1 lb. to 10 lbs	31	10	1,137	34
"	"	Untreated	15	20	388	687

For the above test bluestone was dissolved and mixed with water at the rate of one pound to 2 pails of water. In this solution the seed was dipped. For smutty seed one pound of bluestone was used for six bushels: for clean seed one pound to ten bushels.

FALL WHEATS.

Nine varieties of fall wheat were sown in one of the hedged enclosures on the 21st of September, 1897. All the varieties were above ground when winter set in and came through the winter and spring safely. All made a rank growth and from the large heads formed gave promise of a very heavy yield. Rust, however, struck the straw when the heads were partially filled, causing a very light yield of very poor grain. The soil was clay loam, and the size of the plots $\frac{1}{10}$th acre each. A large snow bank cov-

ering the grain during the winter and the absence of severe spring frosts until the roots had became thoroughly established, accounts for this crop coming through the winter safely.

EXPERIMENTS WITH OATS.

The oat crop this year was not as heavy as that of 1897, caused by spring frosts which twice cut back the various plots, killing a very considerable number of the young plants of the more tender varieties. In several plots from one-third to one-half of the plants were destroyed. All the varieties were thus kept back and ripened much later than usual. In addition to this pigweed obtained a good start, and in several of the acre plots helped to decrease the yield.

The land sown to oats had all been summer-fallowed in 1897, which work consisted of one deep ploughing in May or early in June, and several surface cultivations during the growing season by means of which all weeds were kept in check.

TEST OF EARLY MEDIUM AND LATE SOWINGS.

Banner and Abundance oats were used in this test. The sowings were one week apart and continued from 23rd April to 28th of May. The soil was clay loam, and the size of the plots $\frac{1}{10}$th acre each. The last sowing of Banner and the two last of Abundance were overtaken by frost before maturity, but as the grain was almost ripe very little shrinkage took place. There was no rust on any of these plots.

OATS—FIELD LOTS.

Twelve varieties were sown on fields of one-half to fifteen acres each.

Banner, Abundance, Improved Ligowo and Holstein Prolific gave very heavy crops of straw and with the exception of Improved Ligowo which was badly eaten by blackbirds, yielded well.

The oat plots, large and small, were continually covered with the birds from the time the first heads became ripe until the grain was drawn in and threshed. The plot of Improved Ligowo being near a large dam, suffered more than the other varieties.

All plots were sown on clay loam by hoe-drill at the rate of 2½ bushels per acre. There was no rust on any of these varieties.

OATS.—TEST OF VARIETIES.

Sixty-four varieties were tested on plots of $\frac{1}{10}$ acre each. A number of the plots were injured by spring-frosts and were consequently late in maturing and had not fully ripened when frost came on September 8.

The plots were sown on May 2, on clay loam soil, summer-fallowed land, by hoe-drill at the rate of 2½ bushels of seed per acre. There was no rust on any of these plots.

TEST OF FORMALIN, BORDEAUX MIXTURE AND BLUESTONE AS PREVENTIVES OF SMUT IN OATS.

Three very smutty samples, each of seed of Doncaster Prize, Flying Scotchman and Mortgage Lifter oats, were treated as follows :—

One sample of each was steeped for four hours in Bordeaux Mixture made with one pound of sulphate of copper and one pound of lime in ten gallons water.

Another sample of each was soaked for two hours in a mixture of 3 oz. Formalin in ten gallons water.

The third of each was soaked for two hours in a mixture of 4½ oz. Formalin in ten gallons of water, and for comparison a sample of each of the three varieties was sown without treatment.

Another test of Bordeaux Mixture and Bluestone was made with clean seed of Banner oats.

All these plots were sown side by side, on the same day, on summer-fallow, by hoe drill at the rate of 2½ bushels per acre.

"	"	Bluestone	693	1
"	"	Untreated	746	7

From the above table it will be seen that Bordeaux Mixture and Bluestone were effective in the treatment of clean seed; while Formalin proved a complete remedy with seed which was badly affected by smut.

EXPERIMENTS WITH BARLEY.

Frosts in May made the crop of barley smaller than it would otherwise have been. The test-plots and larger field-lots were several times cut back and a considerable number of the young plants never recovered. Pigweed, in the field-lots also helped to decrease the yield.

Late rains gave large and plump grain in all the varieties, but at the same time caused the grain to be much discolored.

The larger lots of barley were sown on fallow, on a field exposed to winds which, though not so severe as in former seasons, were bad enough, in conjunction with spring frosts, to retard growth and cause the crop to mature unevenly and late.

Results of Early, Medium and Late Sowings.

The two varieties used in this test were Odessa, six-rowed, and Canadian Thorpe, two-rowed. The plots were one-tenth acre each, the soil clay loam, sown on summer-

fallow. The seed was sown by hoe-drill, at the rate of two bushels of seed per acre. The first plots were sown on 23rd April, and the sowings were continued on the same day each week after until 28th May.

The six plots of each variety ripened in the order sown and in time to escape the frost on 8th September. All gave satisfactory yields, with the exception of the first two sowings of Canadian Thorpe which were blighted by hot weather in July. It will be noticed that these two plots were ripe and cut on 11th and 13th August, two days earlier than the first two sowings of Odessa, whereas Odessa usually ripens from four to seven days earlier than the Canadian Thorpe. There was no rust on any of these plots.

BARLEY—FIELD LOTS.

Thirteen varieties were sown in fields of one-half to five acres each. In addition to the injury sustained by frosts in May, winds, which had a clear sweep over these fields, left more or less of the roots exposed, causing the crop to mature unevenly and late. The sample is plump and large but dark in colour.

The seed was sown on clay loam summer-fallowed, by hoe drill, at the rate of 1¾ bushels per acre. There was no rust on any of these fields.

Six-Rowed Barley.—Test of Varieties.

Twenty-three varieties have been included in this test, sown on plots of one-tenth acre each. The soil was clay loam which had been summer-fallowed, and the seed was sown by hoe-drill on the 4th of May, at the rate of two bushels per acre. There was no rust on any of the varieties, but three of them were somewhat injured by smut, namely Common Six-rowed, Stella and Summit.

Two-Rowed Barley.—Test of Varieties.

Eighteen different sorts of two-rowed barley were tested this year on clay loam summer-fallowed, all were sown on 4th May in plots of one tenth acre each. No rust was found on any one of them, and the following yields were obtained.

Two-rowed Barley—Test of Varieties.

TEST OF PREVENTIVES OF SMUT IN BARLEY.

Bordeaux Mixture and a solution of bluestone were used in this test and for comparison a plot was sown with untreated seed. The seed used was ordinary, clean Canadian Thorpe, the product of treated seed sown in 1897.

Variety.	Treatment.	Sown.	On 25 Square Feet.	
			Good Heads.	Smutted Heads.
Canadian Thorpe	Bluestoned	May 6	921	1
"	Bordeaux Mixture	" 6	823	2
"	Untreated	" 6	912	17

The bluestone solution was the one ordinarily used for wheat, one pound of bluestone dissolved in two pails of water for each ten bushels of seed.

Bordeaux Mixture was made in the proportion of 1 pound sulphate of copper, 1 pound lime to 10 gallons water and in this solution the seed was allowed to soak for four hours.

EXPERIMENTS WITH PEASE.

The yield from all the varieties of pease tested was good but the sample was not quite equal to that of former years. Varieties that ripened early were better in this respect than the later sorts.

Heavy rains in July and up to the time of cutting gave the late varieties a most vigorous growth, in consequence of which 13 of them were on the green side when frost occured on September 8th.

On account of rains great difficulty was experienced in harvesting and threshing the various plots. Frosts in May cut back the vines, retarding the growth until rains came in July,

Results of Early Medium and Late Sowings.

The two varieties sown in this test were Golden Vine, a small pea and Mummy a medium sized variety. The soil was clay loam ; seed sown on summerfallow by hoe-drill on the 5th of May, at the rate of 2 bushels of small pease and 3 bushels of medium per acre. The size of the plots was one-tenth acre each. The first plot of Golden Vine and the two first of Mummy were injured by frosts in May.

Pease.—Test of Varieties.

The trial plots of pease sown to gain information as to their relative yield and earliness included forty-eight varieties. These were all sown on one-tenth acre plots. The soil was a clay loam which had been summer-fallowed, and the seed was sown on the 5th of May at the rate of two bushels of the small pease and three bushels of large pease per acre.

EXPERIMENTS WITH INDIAN CORN.

Twenty-five varieties of Indian corn were grown the past year in uniform test plots. The seed was sown by grain drill in rows three feet apart and planted by hand in hills three feet apart each way. The land was a clay loam, fallowed the year previous and manured, in the fall, with 15 loads well rotted barn-yard manure per acre. The work on fallow consisted of one deep ploughing early in June and three surface cultivations with spring-tooth cultivator during the growing season. Early in October the manure was applied and the land again ploughed to a depth of 7 to 8 inches, then harrowed well

and rolled. Before sowing the seed two inches of the surface was stirred by cultivator and harrowed. The corn was sown and planted on May 16th and the plants were two to four inches high when cut back by frost on the 27th of same month. Where the corn was just above ground when cut down the recovery was much more rapid than where the plants had attained a height of several inches.

The difference in results between sowing in rows and planting in hills was not so marked as in former years.

On the whole, the crop was larger than last year but was not so far advanced when it had to be cut for fear of frost. Only one variety had reached the early milk stage when the crop was cut.

All plots were cut on September 7th and 8th and allowed to remain on the ground for two days to wilt before being drawn into the barn when it was cut by ensilage-cutter and put in the silo.

One hundred tons were put in silo, and at present time the ensilage is being mixed with cut straw and fed to stock. The yield per acre, in each case, has been calculated from the weight obtained from two rows each 66 feet long.

TEST OF SOWING AND PLANTING CORN AT DIFFERENT DISTANCES APART.

This test was made on land worked and manured the same as for uniform test of varieties. Three varieties of corn were sown in rows and planted in hills at different distances apart, and from the accompanying table it will be seen that in hills the closer the planting the better the crop, while in rows the reverse was the case.

EXPERIMENTS WITH FLAX.

The experiments with flax were not very satisfactory, the early sown plots being badly injured by frosts in May.

The tests were made on fallow land, clay loam, not manured, and the size of the plots was one-tenth acre each.

EXPERIMENTS WITH GRASSES.

Following are the yields per acre of grasses sown in the spring of 1896 :—

Agropyrum tenerum	2 tons 250 pounds.
" caninum	1 " 860 "
Meadow Fescue	1 " 360 "
Timothy and Alsike Clover	1 " 370 "

AGROPYRUM TENERUM.

On account of this grass having produced good crops in trial plots for the past two years, a field of three acres was seeded down to it early in July. A good catch was obtained and the grass made good progress before winter set in. The seed, like Brome seed, germinates easily, and if not sown too thick will in ordinary seasons produce satisfactory crops of hay for horses. It should, however, be cut before the stem hardens and becomes woody. Cattle do not seem to relish it much, and for fall pasture it is useless.

AWNLESS BROME GRASS (*Bromus Inermis*).

The crop of hay obtained from the fields of Brome grass was the lightest that has been cut on the farm since the introduction of this grass. With the exception of 1¼ acres of first crop, the greater part of the land under Brome grass had produced a crop of seed last year, and the balance had been cut for hay and seed for three and four years. Eight acres of the latter produced only 1,000 pounds cured hay per acre, fields from which one crop had been taken 1,700 pounds per acre, and the 1¼ acres sown last year 2 tons 500 pounds per acre.

The light crop was, no doubt, caused by the dry condition of the land in the fall of 1897 and insufficient rainfall, in April or May of this year, to give the grass a start.

The crop of Brome grass throughout the country was much the same as on the experimental farm. Where the grass was being cut for the first time either for hay or seed, a fair, and in some cases a good crop was secured, whereas fields producing the second, third or fourth crop were very light.

Mr. F. W. Godsal, in the Pincher Creek district, of Alberta, obtained nearly 8,000 pounds of seed. Mr. W. R. Motherwell of Abernethy, Assiniboia, a successful grower of this grass, had between 500 and 600 pounds of seed per acre. To produce these quantities of seed, the crops of hay must necessarily have been very heavy.

For information regarding the seeding of Brome grass the following is quoted from the report for 1896 :

"This grass is better sown alone ; at least it should not be sown with a grain crop. The grain takes too much moisture from the young grass-plants, only the most vigorous of which will survive the dry weather in September; whereas, if sown alone all the plants have an equal chance.

" It is also advisable to sow the seed on soil that does not blow. Summer-fallow would be the best preparation, but on account of its liability to drift it is not safe in many parts of the Territories to use this kind of land. Stubble land ploughed three or four inches deep in April or May, and well harrowed after the seed is sown, is found to be quite safe from winds as the stubble harrowed on top prevents all drifting."

Ten to twelve pounds of seed is required per acre. " More seed will give a better crop the first year, but less afterwards as the roots thicken up each year and in three or four years makes better pasture than hay.

"The seed being light, long and thin, seeding by hand is the only practicable method. To seed properly a calm day should be chosen, so that all parts of the land may be evenly sown.

"While the plants are young, weeds are sure to make great headway and it is necessary to keep them, at least from going to seed. The quickest way to accomplish this is to go over the field with a mower, cutting just above the grass-plants. If this operation has to be repeated it will be necessary to cut the tops of the grass, but this will not injure the plants, in fact it is an advantage in the way of giving the roots a better hold.

" The first crop of hay can be cut the next year after seeding, and will, in ordinary years be ready early in July. Eight or ten days after being ready to cut for hay it will be fit to cut for seed if so desired.

" On this farm it has always been cut in first blossom for hay and ten days from this time it is considered in proper state to cut for seed.

"In cutting for seed a binder is used and the grass is cut, tied and stooked the same as wheat or other grain. In a week or ten days after cutting it is ready to thresh or store away as deemed best.

"For threshing small quantities the old-fashioned flail is suitable, but for large lots a threshing machine should be used on which the wind has been closed off as much as practicable. From three to six hundred pounds of seed may be expected from an acre."

RENEWAL AND ERADICATION OF BROME-GRASS.

Last fall, just before winter set in, one half acre of Brome sod was ploughed four inches deep in as narrow furrows as possible. Four crops of hay had been cut from the plot and the roots had become very thick.

On the 6th May, 1898, Prince Albert pease were sown, harrowed in and rolled. Shortly after the pease were sown the grass commenced to grow very thick, and from that time it was a race between Brome grass and pease, with the result that pease were one-third crop and Brome grass a good catch. The pease and grass were cut by mower and the land left to see what results can be obtained in renewing Brome sod without reseeding. Three-quarters of a ton of pease and Brome hay was cut from the one-half acre.

On 14th, 15th, 16th and 19th April last, 7 acres of Brome sod was ploughed two inches deep. By the time the sod was rotted sufficiently to backset, quite a heavy growth of grass was covering the land. On 16th, 17th, 18th and 20th June, all but one-half acre of this land was backset 4 inches deep. Brome roots continued to grow after the backsetting, and the land was again ploughed before winter set in. The one-half acre not backset had, when the remainder of the plot was ploughed the second time, a good catch of grass which promises a crop of hay next year.

Last spring, after seeding was finished, an old piece of Brome sod was gone over four times with iron harrows to determine whether or not it could be renewed without ploughing. The result clearly demonstrated the impracticability of this method.

As stated in the report of last year, several acres of Brome sod was ploughed on 18th, 19th and 20th May, 1897, and sown to pease at the time or backset later on. That portion sown with pease was ploughed last fall and together with part of the backsetting was sown with Red Fife wheat this spring. The balance of the backsetting was used for potatoes, corn, pease and roots. The wheat averaged 20 bushels per acre and the potatoes, pease, corn and roots yielded one-third less than the same varieties sown on fallowed and manured land.

EXPERIMENTS WITH CLOVERS, ETC., FOR GREEN MANURING.

Recognizing the necessity of making some preparations for manuring the land in the future, when exhaustion of the soil will have taken place through continual cropping, a series of tests was commenced last spring, with a view of finding some plant suitable for soiling purposes.

The land chosen for the test was a five-acre field of clay loam over which winds have a great sweep, and in the past ten years have blown several inches of the top-soil to adjoining farms. The field produced a crop of barley in 1897, and before sowing, this spring, the plots were ploughed six inches deep and well harrowed.

On the 12th May, nine one-half acre plots were sown one each with Red Clover, Alsike Clover, Pease, Tares, Bromus Inermis, Mammoth Clover, Lucerne, Rape and Buckwheat; the remaining one-half acre being left unsown and fallowed later in the season. The seeds in all the plots germinated soon after being sown and made good growth during the months of June, July and August. Weeds were numerous and the mower had to be run over the clover and grass plots several times to keep them in check. This, however, was done without cutting any of the grass or clover plants.

When the pease, tares, rape and buckwheat had attained their maximum growth they were ploughed under and the plots harrowed; later on, when the clovers and grasses had ceased growing they were treated in the same way.

The half-acre plot not seeded was summer-fallowed by one deep ploughing and several surface cultivations during the growing season.

Next spring it is intended to sow the entire field with Red Fife wheat, when some information regarding the value of the various plants for green manuring will be gained by the yield of the plots, which will be cut and threshed separately.

TEST OF CLOVER TREATED WITH NITRAGIN.

Two uniform plots of one-tenth acre each were chosen. The land was a clay loam in one of the garden inclosures which had been prepared for corn and roots.

Clover seed treated with nitragin and similar seed untreated was received from Ottawa early in the season with instructions for carrying on this test. The seed was sown at the rate of 10 lbs. per acre—on one of the plots the seed which had been impregnated with nitragin germs, and on the other the untreated seed. These were both sown 16th June, when the soil was moist and warm, and the seed germinated quickly. By 1st July the "treated seed" plants were 2½ inches high, while the "untreated" were not over 1½ inches. Both plots grew fast and headed out on 1st October. The "treated" plot was much more matted and grew 12 to 15 inches high, whereas the "untreated" did not exceed 12 inches in height.

EXPERIMENT WITH SPRING RYE.

Spring rye was sown on two acres of fallowed land on April 19th, and cut on August 13th. The straw was 40 inches high; its weight was 3,000 lbs. per acre; and the yield of grain was 29 bushels per acre.

EXPERIMENT WITH BUCKWHEAT.

One-tenth of one acre was sown on June 2nd; which produced a heavy crop of straw, but the heads were blighted and did not fill.

EXPERIMENT WITH RAPE.

This was sown May 20th, on a one-tenth acre plot at the rate of 2 lbs of seed per acre, on fallow land manured. Later it was cut and fed to stock. The yield was 16 tons 600 lbs. of green fodder per acre.

EXPERIMENT WITH TARES.

These were sown on fallow on May 19th; and cut on August 31st. Height 55 in.; weight of straw, (dry) 2,740 lbs; seed, 11·40 bushels per acre.

CANARY-GRASS.

This was sown May 19th, on a one-tenth acre plot and cut September 6th. Height 30 inches, yield of hay, 2,900 lbs per acre; seed, 18½ measured bushels per acre.

EXPERIMENTS WITH JAPANESE MILLET, EARLY SOJA BEANS AND HORSE BEANS.

JAPANESE MILLET.

The seed of this millet, also the seed used in the two following tests of Soja Beans and Horse Beans was received early in the season from the Director with instructions for sowing. The chief object in view in these experiments was to gain information as to the relative usefulness of these plants and horse beans as forage crops in this climate, and the weight of crop obtainable from each when sown in different ways.

Three plots of Japanese millet were sown on May 28. In the first the drills were 9 inches apart; in the second 12 inches apart and in the third the seed was sown broadcast. The plots were cut on September 7 and the millet fed to stock. About half of each variety had headed out at this date and the straw was from 39 to 42 inches high. The following yields were obtained :

	Per acre Tons.	Lbs.
1st Plot. Drills 9 inches apart yielded	16	800
2nd Plot. Drills 12 inches apart yielded	14	
3rd Plot. Broadcast	14	800

EARLY SOJA BEANS.

Three plots were first sown May 15 and cut by frost May 27. They were sown again on May 28th. The first plot was sown in drills 2 feet apart, the second $2\frac{1}{2}$ feet apart and in the third the drills were 3 feet apart. All the plots made a fair growth and were just forming pods when destroyed by frost on September 8th.

The frosted beans were weighed after cutting with the following results :

	Lbs. Per acre.
Drills 2 ft. apart yield	1,650
Drills $2\frac{1}{2}$ ft. apart yield	1,325
Drills 3 ft. apart yield	1,275

The weights of these frosted vines gives scarcely a fair idea of what the weights would have been had frost come later.

HORSE BEANS.

These were sown on three plots on May 28, in drills 2 feet, $2\frac{1}{2}$ feet and 3 feet apart, the same as the Soja Beans. The crops were cut September 7th and put into the silo with corn.

The yields from the plots were as follows :—

	Per acre. Tons.	Lbs.
Drills 2 feet apart	3	600
Drills $2\frac{1}{2}$ feet apart	2	1,600
Drills 3 feet apart	2	1,200

POTATOES.

One hundred varieties were tested on land summer-fallowed in 1897. The work on this land consisted of one ploughing 7 inches deep, in the latter part of May, and three surface cultivations 2 to 3 inches deep with spring-toothed harrow during the growing season. From 4th to 8th September, 15 loads (per acre) of well rotted manure was put on, and the land again ploughed 7 to 8 inches deep, well harrowed and rolled.

On May 13 drills were made 4 inches deep and 30 inches apart by plough. In these the cut potatoes were planted 14 inches apart. The pieces had 2 to 3 eyes each, and were from good sized potatoes. The drills were filled in by plough as soon as possible after planting, and the plot was harrowed to level the ground. The land was harrowed when potatoes were appearing, and again a week afterwards. After this the scruffler was run through the rows once a week until the plants became too large to permit of cultivation. The soil was a clay loam. The potatoes were planted on the 13th of May, and dug the 11th of October. The yield per acre has been calculated from the weight of tubers dug from two rows, each 66 feet long; there was no rot in any of the varieties.

EXPERIMENTS WITH ROOTS.

TURNIPS.

Nineteen varieties of turnips were tested. Each variety was sown twice: the first sowing was on May 14, and the second on May 25.

The land for roots was clay loam which had been prepared in the same manner as that for the potatoes, and with the exception of stirring two inches of the surface no work was done on the field in the spring before seeding.

A grain seed drill was used to mark the rows, all teeth being removed except three, which made marks thirty inches apart, in which the seed was sown by a Planet Jr. seed drill at the rate of 2 pounds of seed per acre.

As will be seen, all the varieties gave a satisfactory yield, and with the exception of three, the early seeding gave the best returns. On account of the heavy rainfall, the tops on all the varieties were very rank. The yield per acre was calculated from the weight of roots obtained from two rows, each 66 feet long.

EXPERIMENTS WITH MANGELS.

Eighteen varieties were tested and two sowings were made of each. The soil was clay loam and the preparation of the land was the same as that for the turnips, and the seed was sown in the same way at the rate of four pounds per acre.

The first seeding was well up when frost occurred on 27th May, causing considerable injury to the plants.

Like the turnips, the mangels produced a strong growth of tops and gave satisfactory returns of roots. The yield per acre was estimated from the weight of crop obtained from two rows, each 66 feet long.

EXPERIMENTS WITH CARROTS.

Sixteen varieties were tested in one seeding on uniform plots. The soil was clay loam, prepared the same as for other roots.

While the returns were not large the crop was the best ever grown on the farm. The yield per acre was estimated, as in the case of the other roots, from the weight of crop gathered from two rows, each 66 feet long.

EXPERIMENTS WITH SUGAR BEETS.

Six varieties were sown twice on clay loam prepared as for the other root crops, and the seed was sown at the rate of four pounds per acre.

Danish Improved and Danish Red Top were clean and well shaped roots, the others were rough and rooty.

As will be seen, the late seeding in this instance gave much the best returns.

VEGETABLE GARDEN.

Frosts in the latter part of May did considerable damage to all early vegetables, but the abundant rainfall in June and July ensured a large crop of everything. Cabbage, cauliflowers, onions, celery, lettuce, beets and radishes far surpassed the production of any previous season. Tomatoes were also a good crop but did not mature as early as usual.

ASPARAGUS.

Three varieties, Conover's Colossal, Barr's Mammoth and Donald's Elmira were grown in beds planted in 1891 and 1893. The crop was somewhat below the average on account of dry weather early in the season, but some good cuttings were obtained from all the varieties. First cut 2nd May, continued in use till 25th June.

BEANS.

Eleven varieties were tested.
Sown 6th May and well up 27th May, frozen 27th May. Resown 29th May.

Dwarf White Butter,	in use	August 2.	
Improved Rust-proof,	"	" 4.	
Golden-wax (Simmers),	"	" 3.	
Valentine Wax,	"	July 30.	Good.
Golden Wax (Steele),	"	August 4.	
Wardwell's Kidney Wax,	"	" 6.	The best.
Taber's I.X.L. Green pod.	"	" 4.	
Roger's Lima Wax,	"	July 30.	Good.
Golden Wax (Ferry),	"	August 6.	
Challenge Dwarf Black Wax,		" 8.	
English Broad Windsor,		"	Did not pod.

To save the first seeding from frost, earth was heaped over the vines. Where the covering was less than one inch thick the vines were destroyed: otherwise the plants came through alive but took a long time to recover.

BEETS.

Twelve varieties were sown on May 6th, in drills 18 inches apart. The crop was a large one, but some of the varieties grew thick-skinned and coarse. Lifted Sept. 28th.

Variety.	Fit for Use.	Bush. per Acre.	Remarks.

Plan showing ornamental planting about residence of Superintendent, also hedge enclosures and fruit orchards on Experimental Farm at Indian Head, N.W.T.

CARROTS.

Seven varieties sown April 21. Lifted September 27.

Variety.	Bush. per Acre.	Remarks.
Vaughan's Selected Danvers	405	Rough.
Long Red Stump Rooted	378	Smooth, good.
Large Scarlet Nantes	325	Excellent quality.
Early Scarlet Horn	280	" "
Danvers' Half-long	269	Fair quality.
New York Market	216	" "
Scarlet Chantenay	216	Excellent quality.

CABBAGE.

Sown in hotbed April 5th. Transplanted into frames April 26th. Transplanted into garden May 23rd.

Variety.	Fit for Use.	Remarks.
Red Dutch Pickling	Sept. 2	Good size. Solid heads.
Red Drumhead Pickling	" 2	Solid heads. All headed.
Lightning Express	" 2	Solid large heads. "
Burpee's World-beater	" 14	Very fine large heads.
Early Jersey Wakefield	July 15	Early, solid. All headed.
Early Paris	Aug. 3	Early, a few soft heads.
Early Standard	" 12	Early, solid.
Very Early Etampes	July 27	Early, solid. Even. All headed.
Fottler's Early Drumhead	Aug. 3	" " "
Vandergaw	July 27	Early, solid. One of the best.
Surehead	Aug. 2	" "
Nonesuch	Sept. 12	Late, large fine heads.
Late Drumhead	" 12	" "
Drumhead Savoy	Aug. 2	All solid heads.

SOWN IN COLD-FRAME.

Early Standard, Very Early Etampes, Fottler's Early Drumhead, Surehead, Nonesuch, Burpee's All-head, Early Summer, The Lupton, Large Aubervillier's Savoy, Premium Flat Dutch and Red Dutch were all sown in cold-frame on 26th April, and transplanted to garden 15th June. The crop was just as good as from the plants sown in hotbed and was a great deal less trouble.

CELERY.

Sown in hotbed 6th April. Set out in trenches 20th June.

Pink Plume,	in use	10th September.
White Plume	"	24th August.
Paris Golden Yellow	"	12th September.
Dobbie's Invincible	"	"
Evan's Triumph	"	"
Golden-hearted Dwarf	"	"
White Pascal	"	"
Giant White Solid	"	"
Rose-ribbed Paris	"	"

All varieties produced the largest and best crop of celery ever grown on this farm. White Plume was the earliest and best variety, though the heads were not so large as those of other varieties. All were solid and crisp.

CITRONS.

Two varieties, Red Seed and Colorado Preserving, were sown in hotbed on the 19th April. Potted on 9th May and set out on 22nd May. The Red Seed produced a fair crop of well formed fruit, averaging 8 pounds each. Colorado Preserving was more prolific, the fruit averaged 10 pounds each, but was uneven.

CAULIFLOWER.

The following ten varieties were sown in hotbed on 5th April, transplanted to cold frame 25th April, and set out in garden on 25th May. The same varieties were also sown in cold-frame on 26th April, and set out in garden on 13th June. The crop from plants started in hotbed came into use about ten days earlier than that from the cold-frame plants, but no difference could be noticed in the productiveness or quality.

Variety.	Fit for use.	Remarks.
X. X. X	Aug. 6..	Fine solid heads.
High Grade Erfurt	" 8..	Extra fine quality, but small.
Danish Snowball	" 8..	Very white, close heads.
Earliest Dwarf Erfurt	" 3..	Some fine heads; a few imperfect.
The World's Best Snowball	" 6..	Very close heads; all headed.
Early Snowball	" 4..	Very close heads; a few did not head.
Early Favorite	" 8..	Large fine; a few imperfect.
Extra Early Whitehead	" 3..	Very large heads; all perfect.
Gilt Edge	" 10..	" "
Selected Early Erfurt	" 5..	One of the best; all perfect.

CUCUMBERS.

Sown in boxes in hotbed on 19th April, potted on 9th May, and set out in frames in garden on 19th May. None of the varieties were very prolific, but the fruit was large.

Variety.	Fit for use.	Remarks.
Chicago Giant Goliath	July 14..	Large fruit; few on vines.
Chicago Pickling	" 16..	Very few set.
New Siberian	" 3..	Extra good.
Arlington White Spine	" 10..	"
Giant Pera	" 14..	Good crop; even and large.
White Wonder	" 10..	Good fruit; very few set.
Albino	" 10..	" "
Giant White	" 16..	Largest grown.
Livingston's Emerald	" 11..	One of the best.
Evergreen White Spine	" 10..	Good fruit.
White German	" 9..	Very few set.
No. 23	" 10..	Fair crop.

CORN.

Early Giant Kendall, First of All, The Cory, Early Market, Mitchell's Early, Ford's Early Sugar, Early Cory, Squaw Corn, were planted on 16th May. Fit for use 27th August to 7th September. Cut down by frost on 8th September. No corn ripened. First of All, Squaw Corn and Mitchell's Extra Early were fair crops; the others poor.

LETTUCE.

First seeding May 2. Fit to use June 26.

Second seeding May 13. Fit to use August 5 to 10.

Gardner's Favorite.—Fine large heads.
Big Boston.—The best.
Prize head.—Fine heads.
Toronto Market.—Fine heads.
Large Passion.—Very good.
Early Tennis-ball.—Very good.
Blonde Beauty.— "
Mammoth Cabbagehead.—Fine large heads.
The Deacon.— " "
Black Seeded Butter.— " "

Both seedings gave exceptionally good crops.

MELONS.

Musk Melons:—Early Hackensack, Grand Rapids, Emerald Gem and Earliest of All, sown in boxes in hotbed April 19. Transplanted to frames in garden May 19th. Crop good but fruit small.

Water Melons:—Glory of Asia and Phinney's Early, sown in boxes April 19th. Transplanted to frames in garden May 9th. Small crop of good sized fruit. Frames were put over vines on Sept. 1st and the fruit ripened under glass.

MARROWS AND SQUASH.

Mammoth White, Summer Crookneck, Mammoth Chili Squash, and Long White and Early Yellow Bush Marrows were sown in frames in garden on May 13. All produced a fair crop of good sized fruit.

PUMPKINS.

Mammoth King and Connecticut Field pumpkins were sown in frames in garden on May 13. A fair crop of large sized, imperfectly matured pumpkins was the result.

BRUSSELS SPROUTS.

New Giant sown in hotbed April 5. Transplanted to garden May 23. Good crop.

PEPPER.

Cardinal and Long Red sown in hotbed April 5. Potted May 11 and set out May 26th. Neither variety ripened although a large crop of fruit set.

HERBS.

Summer Savory, Mint, Sweet Marjoram and Cress sown on April 21. All did well.

ONIONS.

Sown in hotbed April 4th. Transplanted May 26th. Lifted September 23rd.

Variety.	Bush. per Acre.	Remarks.
New White Victoria	756	Very large. Fair quality.
Prize-taker	756	" Good shape.
White Globe	680	" Good quality.
Large Red Wethersfield	621	Large and even. "
Yellow Globe Danvers	594	"
Cracker Jack	594	Fair size. Good quality.
Sutton's White Leviathan	594	Large size. Fair quality.
Dobbie's Golden Globe	511	Fair size. Good quality.
King of the Earliest	485	Early and good quality.
Giant Rocco	....	Did not grow.

Sown in the open. Sown April 23rd.

Variety.	Bush. per Acre.	Remarks.
Prizetaker	537	Very large but soft.
White Globe	511	Very large. Solid.
Large Red Globe	459	Good crop. Solid.
Yellow Globe Danvers	432	" "
King of the Earliest	432	Fair size. Good crop.
Dwarf Golden Globe	432	Very large.
Oxonion	405	Very fine onions.
Cracker Jack	378	Fair size. Medium quality.
Large Red Wethersfield	378	Good crop.
Large Yellow Flat Danvers	351	Extra fine.
Early Red Wethersfield	270	Firm. All good.
The Queen	162	Good crop. Picklers.

ONION SETTS.

White Multiplier, White Dutch, Red Setts, Bruce's Yellow, Vaughan's Yellow and Simmers' Yellow were set out on 20th April and produced a good crop. White Multipliers were extra fine.

PEASE.

Eleven varieties were sown on 29th April and again on 6th May.

Variety.	1st Seeding fit for use.	Ripe.	Remarks.
Daisy	July 18	Sept. 6	Best variety.
C. P. R	" 26	....	Good green pea. Too late to ripen.
American Wonder	" 9	Sept. 1	Good early pea.
Anticipation	" 26	....	Good green pea. Too late to ripen.
Horsford's Market Garden	" 16	Sept. 7	Good crop, but late.
Alaska	" 9	" 1	Good variety, small.
Nott's Excelsior	" 16	" 7	Good late variety, large and sweet.
Imp. Stratagem	" 25	" 7	Good late variety.
Wm. Hurst	" 9	Aug 31	Best early variety.
Laxton's Charmer	" 25	Sept. 8	Fair late variety.
Heroine	" 25	" 9	Good variety, but too late.

TOBACCO.

Connecticut Seed Leaf sown in hotbed 8th April. Cut 27th August. Good leaf. Will be useful for spraying maple trees for aphis.

PARSNIPS.

Sown 21st April. Lifted 28th October. Dobbie's Selected, 756 bushels per acre, best, even, thick roots; Hollow Crown, 680 bushels per acre, second best, long, thick roots; Maltese, 432 bushels per acre, good quality.

RADISHES.

Ten varieties were sown on 2nd May and again on 13th May, but were cut down by frost on 27th May. The same varieties were resown on 29th May and the crop produced surpassed all previous crops of radishes grown here.

All varieties were fit to use six weeks after seeding.

Rosy Gem; extra good.
Golden Turnip; good.
Early White Lipped; good.
New Pearl Forcing; fair.
Early Scarlet Globe; extra good.
In and Out; extra good.
Extra Early White Olive; one of the best.
Long White Vienna; good.
Rosy Gem (Simmers); extra good.

RHUBARB.

The old bed of Linnæus and the beds of Large Green and Victoria set out last year did well considering the season. A number of the roots of all the varieties died during the summer. Large Green is a large, coarse variety; the other two are very fine.

TOMATOES.

Sown in hotbed 8th April. Repotted 11th May. Set out 30th May, Yellow Plum. Fair crop. Did not ripen.

Earliest of all.	Ripe August	17.	Fair crop.	Imperial.	Ripe August	24.	Fair crop.
Atlantic Prize.	"	29.	"	Dominion Day.	"	24.	"
Early Michigan.	"	25.	"	New Sensation.	"	24.	"
Early Ruby.	"	29.	"				

A few tomatoes of the above varieties were ripe on the dates mentioned, but the greater part of the crop was ripened under glass which was put over vines on 1st September.

FLOWER GARDEN.

In no previous year have we had such a profusion of flowers as during the past season. Commencing in May with a large bed of Tulips there was continuous bloom till snow fell and covered the Pansies. The Tulips were followed by Sweet Williams, Pansies, Dianthus, Phlox, Sweet Peas, Stocks, Verbenas, Petunias and other flowers of equal beauty. Asters alone, among all the varieties tested, did not do well and very few were in bloom when the plants were cut down by frost on September 7th.

The Tulips planted last year were a great success and the variety of colours and size of flowers were a source of pleasure to every one.

Eschscholtzia was also very fine and used as a border produced a very pretty combination of bright yellow, white and purple flowers.

ANNUALS.

Sown in hotbed and transplanted. Sown April 9, transplanted June 25.

Variety.	In Bloom.		Remarks.
	From	To	
Asters	Aug. 23	Sept. 7	Very few flowered.
Carnation Marguerite	" 28	" 7	Flowers small.
Dianthus	" 5	" 7	Very fine.
Stocks	July 19	" 7	"
Pansies	May 15	Nov	"
Antirrhinum	Aug. 15	Sept. 7	Fair show.
Petunia	" 15	" 7	Fine. Not many double.
Verbena	" 10	" 7	Much finer than previously grown.
Linum, Scarlet	" 10	" 7	Good.
Calliopsis			Very fine.
Zinnia			Not as good as usual.
Phlox Drummondi			Extra fine.

Sown in Open

The following were sown in open ground May 20 to 25th. All flowered well and made a good show until frozen:—Sweet Peas, Nasturtium, Sweet Alyssum, Phlox Drummondi, Candytuft, Mignonette, Poppy, Godetia, Salpiglossis and Larkspur.

For gardens in the North-west Territories the following are recommended:—

For sowing in hotbed and transplanting: Stocks, Pansies, Dianthus, Petunias, Verbenas, Calliopsis, Linum Scarlet, Phlox Drummondi, Dahlia, Antirrhinum and Asters.

For Sowing in the Open.

Sweet Peas, Dwarf Nasturtium, Sweet Alyssum, Eschscholtzia, Candytuft, Mignonette, Poppies, Pansies, Godetia, Salpiglossis, Convolvulus Minor, and Larkspur.

PERENNIALS.

Pæony, Scarlet Lychnis, Yellow Flax, Rudbeckia Golden Glow, Sweet William, Columbine, Iceland Poppy, Everlasting Pea, Perennial Flax, Delphinium Grandiflorum, Platycodon Grandiflora and Larkspur.

BULBS.

Tulips, Scilla Sibirica, Irises, and Crocuses.

PERENNIALS.

(From Experimental Farm, Brandon.)

In May last the following perennials were received from Experimental Farm, Brandon, Manitoba, and set out in permanent bed :—

10	*Hemerocallis fulva*—3 grew well.	4	*Eryngium macrocarpa*—3 grew. No flower.
2	*Veronica salurgoides*—Flowered freely.	20	*Coreopsis lanceolata*—3 grew. Very fine.
10	*Grass Pinks*—Flowered freely.	3	*Hesperis matronalis*—2 grew. "
1	*Dictamnus fraxinella*—Died.	25	*Polemonium reptans*—Flowered. "
1	*Dielytra spectabilis*—Died.	3	*Lychnis Haageana H.*— " "
1	*Allium stellarianum*—Grew.	6	*Perennial Larkspur*— " freely.
3	*Aconitum napellus*—1 flowered late.	6	*Viola pedata*—3 " "
8	*Papaver orientale*—2 grew.. No flowers	6	*Campanula Grossekii*—3 " "
7	*Lychnis Chalcedonica*—1 grew.		Fine.

This fall a large collection of perennials was received from the Central Experimental Farm, Ottawa and planted on 10th October.

BULBS.

A collection of Lilies consisting of sixteen varieties, was received from the Central Farm at Ottawa in October, 1897. They were, however, frozen in transit and having arrived too late to be set out were buried in sand in the root cellar. When opened this spring all the bulbs were found to be completely destroyed.

FOREST TREES.

All varieties of trees and shrubs made a most vigorous growth during the past season. Starting early and growing late without a setback and with an abundance of rain, the largest growth of any one year since the farm started has been attained.

In all probability the late growth will be found, next spring, to have been injurious if not fatal, to many of the trees as the wood did not ripen so thoroughly as in shorter and drier seasons.

The American Cottonwood (*Populus Deltoidea*) rushed ahead as soon as spring opened and the growth during the season was in excess of any previous year.

Russian Poplar (*Populus Bereolensis*), which heretofore had given such good satisfaction and promised to be one of the best varieties of trees for the North-west Territories, did not hold its own and the specimens planted in the open failed altogether.

Among the avenues no losses took place except in the avenue of Russian Poplar and one fine native maple tree (*Acer Negundo*) which had been girdled by boys.

The avenue hedges, especially those set out in 1896 and 1897 made very gratifying progress. Ten miles of roads on the farm are now lined by avenues of single trees or hedges.

In the spring of 1895 five ½ acre plots were planted with trees at different distances apart, for the purpose of ascertaining the cost of planting and caring for the

trees until the ground is sufficiently shaded to prevent the growth of weeds, and hence need no further cultivation.

The trees were planted as follows :—

Plot No. 1,	Box Elder, set out	2½	feet apart each way.
" 2	"	3	"
" 3	"	3½	"
" 4	"	4	"
" 5	Green Ash, set out	2½	"

In addition to these were plot No. 6, ½ acre Box Elder seed, sown in rows 2½ feet apart, and plot No. 7, ½ acre Green Ash seed, sown in rows 2½ feet apart.

Following will be found the cost of planting and taking care of trees for the first, second, third and fourth years.

PLOT No. 1—½ ACRE.

Cost of taking up trees		$0 76
1st year, cost of planting,	15 hours	2 25
" scruffling, &c.	12 "	1 80
2nd year "	10 "	1 50
3rd " "	6 "	0 90
4th " " around plot	1 "	0 15
		$7 36

PLOT No. 2—½ ACRE.

Cost of taking up trees		$0 70
1st year, cost of planting,	12 hours	1 80
" scruffling, &c.	15 "	2 25
2nd " "	13 "	1 95
3rd " "	5 "	0 75
4th " " around plot	1 "	0 15
		$7 60

PLOT No. 3—½ ACRE.

Cost of taking up trees		$0 61
1st year, cost of planting,	9 hours	1 35
" scruffling, &c.	11 "	1 65
2nd " "	12 "	1 80
3rd " "	4 "	0 60
4th " "	1 "	0 15
" " hoeing	3 "	0 45
		$6 61

PLOT No. 4—½ ACRE.

Cost of taking up trees		$0 55
1st year, cost of planting,	9 hours	1 35
" scruffling, &c.	10 "	1 50
2nd " "	14 "	2 10
3rd " "	3 "	0 45
4th " "	1 "	0 15
" " hoeing	3 "	0 45
		$6 55

Plot No. 5—½ Acre.

Cost of taking up trees			$0 76
1st year, cost of planting,	18 hours		2 50
" scruffling, &c.	11 "		1 65
2nd " "	9 "		1 35
3rd " "	5 "		0 75
4th " "	1 "		0 15
" " hoeing	3 "		0 45
			$7 61

Plot No. 6—½ Acre Seed.

1st year, cost of making drills,	2 hours	0 30
" " sowing seed	4 "	0 60
" " covering seed	6 "	0 90
" " scruffling, &c.	11½ "	1 72
2nd " "	10 "	1 50

4th " "	1 "	0 15
		$5 92

Plot No. 7—½ Acre Seed.

1st year, cost of making drills,	2 hours	$0 30
" " cost of sowing seed,	4 "	0 60
" " cost of covering seed	6 "	0 90
" " cost of scruffling, &c.	10½ "	1 57
2nd " "	9½ "	1 42
3rd " "	12 "	1 80
4th " "	1½ "	0 22
" " hoeing	15 "	2 25
		$9 06

The trees did remarkably well, and these plantations will, in a short time, be among the best on the farm.

Plots No. 1 and 2 required no work this year, with the exception of one scruffling around the plots to kill weeds.

Plots No. 3, 4 and 5 were scruffled and hoed. The latter being planted with green ash suffered from frost in May, which retarded growth, but eventually the plot made excellent progress.

Plot No. 6 (maple seedlings) required only one scruffling, while plot No. 7 (green ash seedlings) was scruffled twice and hoed three times.

NEW PLANTATION.

A new plantation, three-quarters of an acre in extent, was set out last spring with maple, ash and elm, and sand-cherry, which is intended to shade the grounds. Sand-cherry was planted in each alternate row with maple, ash and elm, in the proportion of two maples to one of ash or elm in the other rows. A few elms died shortly after being set out, but the blanks will be filled in spring of 1899.

View on Experimental Farm, Indian Head, N.W.T., showing Hedge Enclosures for protecting vegetables and small fruits.

ARBORETUM.

The arboretum now contains 230 species and varieties of trees and shrubs, which have been planted as follows:—

In 1895, 41 varieties; in 1896, 65 varieties, 6 of which replaced deaths of 1895; in 1897, 75 varieties, 2 of which replaced deaths of 1896, and in 1898, 62 varieties, 5 of which replaced deaths of 1897.

The varieties and species added in 1898 are:—

Abies subalpina (from Laggan, B.C.)
Acer spicatum.
Betula (from Niemetz)
" populifolia.
" rubra.
Berberis Cretica.
" Amurensis.
" Sieboldii.
Caragana frutescens.
Celastrus articulata.
" scandens.
Crataegus No. 9 (from Niemetz).
Cephalanthus occidentalis.
Cytisus nigricans longispicata.
" trifolius.
Cotoneaster No. 10 (Niemetz).
Celtis Audiberti.
Cornus Baileyi.
Gymnocladus Canadensis.
Juglans nigra.
Lycium Chinensis.
Ligustrum Amurensis.
Lonicera gracilis.
Magnus (Black Currant.)
Ptelea trifoliata (Russian Form)
Picea Alcockiana.
Pyrus rivularis (B.C.)
" betulaefolia.
Populus balsamifera Suaveolens.
" nigra.
Prunus tomentosa.
Pinus cembra.
" Murrayana (from Banff).
Ribes Siberica.
" alpinum.
" Gordonianum.
Rhamnus No. 13 (from Niemetz).
Rosa blanda.
" villosa pomifera.
Shepherdia argentea (Red Fruit).
" " (Yellow Fruit).
Spiræa tomentosa.
" sorbifolia.
" ulmifolia.
" ariaefolia.
Syringa pekinensis.
Sambucus laciniata.
" No. 45 (from Niemetz).
Salix longifolia argyophylla.
" Sieboldiana.
" nigricans.
" capraea.
" batavaea.
" Salamoni.
" Nicholsoni purpurescens.
" alba.
" villarsiana.
" repens argentea.
" Forbyana.
Tamarix Amurensis.
Viburnum opulus sterilis.

HEDGES.

One species, Ligustrum Amurense, was this year added to the list of sample-hedges.

ROSES.

Of the twelve varieties of Roses planted in 1897, only four survived the winter. In the fall of 1897 the plants were surrounded by frames into which leaves were packed to a depth of 10 to 12 inches. A snow bank four feet deep also covered the plants.

Following are the surviving varieties with notes on their progress during the past season:—

Lady Helen Stewart, made fair growth but did not bloom.
François Levèt, " "
Madame Victor Verdier, " "
Madame Plantier, made very strong growth, but did not bloom.

FRUIT TREES AND BUSHES.

The season has beeen very unfavourable for fruiting, but exceptionally good for growth, and all varieties of fruit trees and bushes have made rapid progress. There was a large show of blossoms in May, but the frosts on 27th, 28th and 29th of that month killed all except native raspberries which bloom late, and cultivated varieties of red and white currants, gooseberries and raspberries, which produced one-third of an average crop. Black currants were completely destroyed.

FRUIT TREES—CRAB APPLES (*Pyrus baccata*).

The first crab apples ever produced on the farm were grown this year. Needless to say, they were not large, but nevertheless, were perfect apples. Ten trees of Pyrus baccata were fairly well covered with blossoms, but frosts late in May killed all except a few blossoms on one tree from which six crab apples were secured.

PYRUS TREES PLANTED IN 1896.

The following notes show the condition and growth of the Pyrus trees planted in 1896. Received from C. E. F., Ottawa.

Name of Variety.	No. Planted. — Spring, 1896.	No. Living. — Fall, 1898.	Notes on Growth.
Pyrus prunifolia	4	4	Strong growth from tips.
Pyrus baccata edulis..................	4	4	3 strong growth, 1 winter killed.
" " flava..................	1	1	Strong growth healthy.
" " sanguinea	8	7	" "
" " lutea Regel	2	1	Fair growth, kills back ½,
" " genuina................	5	5	Strong growth.
" " cerasiformis....	7	6	" does not kill back.
" prunifola intermedia............	4	4	2 " 2 fair growth.
" " xanthocarpa......	4	4	Strong growth.
" baccata macrocarpa............	3	2	" " healthy.
" " aurantiaca.............	2	2	" " "
" " conocarpa	1	1	" "

SEEDLINGS RAISED AT INDIAN HEAD.

Pyrus prunifolia	19	19	Very strong growth.
" baccata macrocarpa............	8	8	"
" " genuina	8	8	"
" " cerasiformus	13	13	"
" " sanguinea	5	5	"

SEEDLING PLUM AND PYRUS ORCHARDS. COMMENCED IN 1897.

The following will be found a list of the trees added to this orchard in the spring of 1898, with notes on the progress of all varieties of trees in the plots.

Planted 1898.—Cross-bred varieties.

—	Number Planted.	Female.	Male.	Progress.
Row 9......	1	Pyrus baccata	Duchess..................	Fair growth.
	6	"	Wealthy......	Strong "
	4	"	Red Astrachan............	" "
	2	"	Martha Crab.......	Fair "
	2	"	Excelsior....	" "
	4	Pyrus prunifolia	Pewaukee	Strong "
	1	Pyrus baccata	McMahon's White........	Weak "
Row 10	11	Pyrus baccata	Tetofsky	6 strong, 5 fair gowth.
	9	"	Talman Sweet............	7 " 2 "
Row 11.........	1	Pyrus baccata	Yellow Transparent... ..	Strong growth.
	6	"	Swayzie Pomme Gris	4 strong, 2 fair growth.
	5	"	Pewaukee	All strong growth.

Root Grafts.

(Made by grafting scions of some of the more promising of the new cross-bred varieties, on Pyrus baccata or Pyrus prunifolia roots.)

No. planted.	Scion of — Female.	Scion of — Male.	Grafted on Root of	Registered No.	Remarks.
	Row No. 11.				
4	Pyrus baccata	Transcendent	Pyrus prunifolia....	29	Did not grow.
4	"	Wealthy	" baccata	145	2 did not grow ; 1 strong growth ; 1 fair growth.
	Row No. 12.				
3	Pyrus baccata	Duchess	" prunifolia....	142	1 living ; made fair growth.

	Row No. 15.				
2	Pyrus baccata	Red Anis...........	" "	161	"
12	Pyrus, No. 529		....	......	9 growing ; 7 fair growth ; 2 weak growth.

There are still nine rows to be planted in this orchard.

Trees planted in orchard in spring of 1897.

The blanks caused by the deaths of trees in 1897 and the winter of 1897-8 were this spring filled with seedlings of the same varieties grown on this farm.

Out of 1,120 trees living in the fall of 1897 only 20 died during the winter and spring of 1897-8, and these deaths were mainly due to water standing on one of the orchard plots for some time in the spring.

The Caragana Arborescens and Lilac hedges around these four orchard plots are making good progress.

PLUMS.

Seedlings of Weaver.—Planted spring 1894. Twelve trees blossomed, seven of which bore fruit which did not mature and was destroyed by frost in September. The fruit was considerably larger than the Manitoba native wild plum but was not nearly matured when frozen.

Seedlings of Hungarian.—Planted 1894. These trees made a strong and healthy growth but did not bear fruit.

Seedlings of Speer.—Planted 1895. Made very strong growth but have not yet borne fruit.

Seedlings of De Soto.—Planted 1895. Have made strong growth but have not borne fruit.

Seedlings of Voronesh.—Planted 1897. All made very strong growth and are in a healthy condition, but have not yet fruited.

Seedlings of Imperial Blue.—Planted 1895. Partly winter-killed but made some very strong shoots this season.

PLUMS from Central Experimental Farm. Planted 1897.

Variety.	No. Planted.	Remarks.
De Soto	2	Very strong growth.
Aikin	1	Killed back; weak growth from root.
Hoskin	1	Lived to near tip and made very strong growth.

PLUMS received from Chas. Luedloff, *Cologne, Minnesota.* Planted 1896.

Variety.	No. Planted.	No. Living last Report.	Remarks.
Purple Yosemite	2	2	2 strong growth.
Clinton	2	1	1 weak growth.
Missouri Apricot	2	2	Grafted on Sand Cherry and growing from stock.
Deep Creek	2	2	2 strong growth.
Irene	2	2	2 fair growth; kills back.
Milton	2	1	1 strong growth.
Anthony	2	2	2 "
Cottrell	2	2	2 "
Emerson	2	2	Grafted on Sand Cherry and growing from stock.
Weaver	2	2	2 strong growth.
Van Buren	2	2	2 "
Reed	2	2	2 "

MANITOBA NATIVE PLUM SEEDLINGS.

Grown from seed planted on Experimental Farm, Indian Head.

Transplanted 1895.

Five trees bore fruit this season. Several others were covered with bloom which was destroyed by frost in May. Fruit on three of the five trees was of fair size and quality; on the other two the plums were small and sour. All matured in good time.

CHERRIES.

Seedlings of Carnation.—Planted 1894. The tree planted in garden enclosure again came through the winter safely and made fair growth, but did not blossom.

Seedlings of Lithaur Weichsell.—The six trees planted in 1894 have made strong growth this season and appear to be gradually becoming hardier, but have not fruited.

Seedlings of Olivet.—Two of the four trees planted in 1895 and reported dead in 1897 shot up from roots this year and made strong growth.

Seedlings of Minnesota Ostheim.—35 planted in 1895. 11 living in 1897 and survived last winter, making very satisfactory growth this year.

Rocky Mountain Cherry.—Planted 1895.

Tree No.	1.	Large crop of small fruit.			Late.
do	2.	Fair	do		do
do	3.	Very heavy crop of large fruit.			Early.
do	4.	Small crop of medium fruit.			Late.
do	5.	Large	do	do	do
do	6.	do	do	large fruit.	Ripe August 25.
do	7.	Small	do	do	
do	8.	Fair	do	small fruit.	
do	9.	Large	do	do	Late.
do	10.	Fair	do	large fruit.	Early.
do	11.	do	do	small fruit.	
do	12.	do	do	do	
do	13.	do	do	do	

The fruit is of good flavour and promises to be a valuable addition to the list of fruits easily grown in the North-west Territories. The bushes made very strong growth during the season and fully matured their wood.

Wild Cherry from Nebraska.—Planted 1896. Hardy and strong grower, but has not yet fruited.

Sand Cherry.—A number of the sand cherries planted in 1894 bore fruit this season. The fruit is not so large as that of the Rocky Mountain cherry, but promises to improve under cultivation. It is valuable for jellies.

Mahaleb cherry.—Planted 1897. Fair growth, kills back one-half.

APRICOTS.

Two trees from Turkestan, planted in spring of 1897, lived through the winter and made fair growth.

PEARS.

Longworth.—Planted spring 1897. Winter killed to near ground, and made very weak growth this season.

GRAPES.

Gibb and Bacchus, planted 1895. Growing slowly.

Manitoba Native Wild, planted 1895, making strong growth, but has not yet fruited.

SMALL FRUITS.

WHITE CURRANTS.

White Transparent, planted 1896. Strong growth. Fruited.
White Grape, planted 1896. Fair growth. No fruit.
White Imperial, planted 1897. Fair growth. No fruit.

RED CURRANTS.

Planted in 1896.

Wilder	3	bushes.	Fair growth.	Fruited.

Sir John	2 "	All dead.	Saunder's Large Red	2 canes.	Both dead.

BLACK AND PURPLE CAP RASPBERRIES.

Schaffer's Colossal and Early Ohio bore a small crop of fruit. Berries small and of medium quality.

Planted 1897.

Charles, 1 plant—Dead.
Royal, 1 do do

GOOSEBERRIES.

Planted 1893.

Smith's Improved.—	Strg. growth.	Fair crop.	Columbus.—	Fair growth	Small crop.
Lancashire Lad.—	Fair growth.	Small crop.	Houghton.—	Strong growth.	Fair crop.
Governess	"	"	Native	"	"

Gooseberries Planted 1897.

Golden Prolific.—	1	weak growth.
Keepsake	2	do
Pearl	2	strong growth.

STRAWBERRIES.

Planted 1895.

Windsor Chief, New Dominion and Pine Apple bore a very small crop of inferior fruit.

Planted 1897.

Scarlet Queen, Brandywine, Gem P., Paris King, Wm. Belt, H. W. Becher, Alpine No. 5. Set out in garden, spring of 1898. Plants healthy and made good growth but did not fruit.

CATTLE.

The herd on the farm at present consists of three Shorthorn bulls and six females; one Ayrshire bull and three Holstein bulls; also three Ayrshire grades, one Holstein grade, one Polled Angus grade and twenty-three Shorthorn grades of which sixteen are two or three-year old steers.

The pure-bred Shorthorns have all been raised on the farm, with the exception of the young bull "Lord Wolseley" just obtained from the Hon. Thomas Greenway, of Crystal City, Manitoba. This bull is from one of the prize-winning cows of the noted Crystal City herd.

On 5th April of this year, an auction sale of stock was held on the farm at which one pure-bred Shorthorn bull, one Polled Angus cow, one Holstein bull and ten Holstein females were disposed of. The following are the names of animals sold:—

Shorthorn bull —"Lord of Qu'Appelle."
Polled Angus cow—"Maid of Skene."
Holstein bull—"Prairie King."
Holstein cow—"Abi."
do —"Siepkje 3rd Queen."
do —"Abi of Assiniboia."
do —"Princess of Assiniboia."
Holstein cow—"Pride of Assiniboia."
do —"Lady of Assiniboia."
Holstein heifer—"Daisy of Assiniboia."
do —"Favorite of Assiniboia."
do —"Pride of Assiniboia 2nd."
do —"Lady of Assiniboia 2nd."

Shortly after the sale the old Holstein bull "Netherland of Brandon" and a Shorthorn bull calf "Katepwe" were disposed of by private sale.

Early in the spring the Ayrshire bull-calf "Dandy Joe of Brandon," obtained from the experimental farm, Brandon, was seriously injured while in the yard with other young stock, and after two months of veterinary attention had to be destroyed. This fall a young Ayrshire bull, "Sir Sydney," has been obtained from the Central Experimental Farm, Ottawa.

The following pure-bred bulls are kept on the farm for service:—

Shorthorn,	"Knight of QuA'ppelle."
"	"Lord Wolseley."
Holstein,	"Earl of Edgeley."
"	"Prince of the Prairie 2nd."
Ayrshire,	"Sir Sydney."

In November fourteen head of Shorthorn grade steers rising three years were secured from Messrs. Gordon and Ironside, of Winnipeg, for use in the feeding tests to be carried on during the winter. To these will be added two grade steers of the same

View on Experimental Farm, Indian Head, N.W.T., showing avenue of Manitoba Maples (*Negundo aceroides*) seven years growth from seed.

age raised on the farm, making three lots of four steers each and two lots of two each. The lots of four each will be fed rations of wheat straw, barley straw and oat straw, and those of two each on Bromus Inermis (Brome grass) and native hay. Each of the above will be supplemented by rations of corn-ensilage and meal.

TEST OF HERD FOR TUBERCULOSIS.

During the month of November, 1897, acting under instructions received from Ottawa, the services of Inspector Burnett and an assistant, of the veterinary department of the North-west Mounted Police, were secured and the tuberculin test applied to all the cattle on the farm. Of the fifty-two animals tested, two only, "Prairie Wildflower," a pure-bred Shorthorn cow, and "Abi 2nd of Assiniboia," a pure-bred Holstein cow, reacted and, by order of the Hon. Minister of Agriculture, were destroyed. Both animals had been tested in 1894 and did not then react.

EXPERIMENTS IN THE FEEDING OF STEERS.

Twelve head of three-year-old steers were divided into four lots of three each and fed from November 13th, 1897, to March 5th, 1898.

Lot No. 1 was fed Brome hay and ensilage;
Lot No. 2 was fed wheat chaff and ensilage;
Lot No. 3 was fed threshed Brome grass, ensilage and bran, and
Lot No. 4 was fed native hay, ensilage and bran.

To each of the animals fed as above was given the same ration of ensilage and in addition two pounds of meal per day during the second month, four pounds during the third month and six pounds per day during the last month of the test. The rations were in the proportion of two pounds ensilage to each pound of dry feed. The meal consisted of two parts ground barley and one part ground wheat.

The animals were fed three times a day and were fed on a uniform ration for two weeks before the test was begun.

MONTHLY AND TOTAL GAINS OF EACH LOT OF STEERS.

Lot No.	Principal Ration.	Gain. December	Gain. January.	Gain. February.	Gain. March.	Gain. Total.
1	Brome hay	130	45	165	90	430
2	Wheat chaff	.....	95	110	110	315
3	Threshed Brome hay	10	165	150	30	355
4	Native hay	60	190	145	65	460

The total amount and estimated value of feed consumed during the feeding period of 112 days was as follows:—

LOT FED ON BROME-HAY.

10,432 lbs.	Ensilage at \$2 per ton	\$10 43
5,344 "	Brome-hay at \$5 per ton	13 36
933 "	Meal at $\frac{2}{3}$c. per lb	6 22
		30 01

LOT FED ON THRESHED BROME-HAY.

10,432 lbs.	Ensilage at $2 per ton	10 43
5,344 "	Threshed Brome-hay at $4 per ton	10 69
933 "	Meal at ⅔c. per lb	6 22
500 "	Bran at $14 per ton	3 50
		30 84

LOT FED ON NATIVE HAY.

10,432 lbs.	Ensilage at $2 per ton	10 43
5,344 "	Native hay at $5 per ton	13 36
933 "	Meal at ⅔c. per lb	6 22
500 "	Bran at $14 per ton	3 50
		33 51

LOT FED ON WHEAT-CHAFF.

10,432 lbs.	Ensilage at $2 per ton	10 43
5,344 "	Wheat chaff at $2 per ton	5 34
933 "	Meal at ⅔c. per lb	6 22
		21 99

SUMMARY OF RESULTS.

Lot.	First Cost.	Value of Feed Consumed.	Total Cost.	Sold for.	Profit on Lot.
	$ cts.	$ cts.	$ cts.	$ cts.	$ cts.
3 steers fed on Brome hay	99 00	30 01	129 01	156 40	27 39

3 " wheat chaff	97 76¼	21 99	119 75¼	164 40	44 64¾

SWINE.

The herd on the farm consists of twelve animals as follows:—

Improved Chester White	1 boar.		
Berkshire	1 "	2 sows.	
Large Yorkshire	1 "	1 "	1 barrow.
Tamworth	2 "	2 "	1 "

Since my last report one Berkshire boar, two Large Yorkshire boars, five Large Yorkshire sows and two Tamworth sows have been sold to farmers for breeding purposes.

POULTRY.

Four breeds are kept, Plymouth Rock, White Wyandotte, White Leghorn and Black Minorca. The breeding pens were made up on March 10th and eggs were gathered as follows:—

Breed.	March.	April.	May.	June.	July.	August.	Total.
Plymouth Rock	35	96	108	....	45	23	307
White Wyandotte	26	82	76	....	32	20	236
White Leghorn	25	73	104	12	39	19	272
Black Minorca	22	52	84	....	24	22	204

The hens were allowed to run together after August 31st. Seventeen cockerels, eleven pullets and twenty-seven settings of eggs were sold to farmers during the year.

THE FLOCK NOW CONSISTS OF

Plymouth Rocks	19 birds.
White Wyandotte	16 "
White Leghorn	18 "
Black Minorca	10 "

HORSES.

At present there are nine heavy working horses, two carriage horses, two 2-year-old colts, one colt 6 months old, and one herd pony on the farm. In the spring the two 2-year-olds will be able to take the place of a team of the older animals which were brought up when the farm was started and are now too old to be of much value.

BEES.

Not much success can be reported in bee culture. Last fall three hives were put in the Superintendent's house in an unused room where the temperature could be regulated. All came through the winter safely and early in May started work on the poplar.

Only one swarm was obtained during the summer.

Two of the old swarms and the new one were well supplied with honey for the winter when put away this fall. The other swarms, however, had very little and the deficiency had to be made up from the stronger hives.

The two old swarms weighed 50 lbs. each and the new one, which is in a small hive, 40 lbs. when stored for winter.

Supers were put on during June, but except in the new hive no honey was stored. The new swarm partially filled six one-lb. sections, excepting which no honey was obtained from any of the swarms.

WEEDS.

During the past season weeds on the farm have not been more troublesome than in previous years. Tumbling Mustard, which for several years has been the cause of much expense, gave very little trouble as the trees on the west and north side of the farm keep all perambulating specimens from being blown in. Stink-weed was rather more abundant than usual, but all plants are being attended to as well as possible. Pigweed was the cause of a decreased yield in several acre plots of oats and barley, the weeds having obtained a start when the grain was cut down by frost. Pigweed was very prevalent throughout the country and in many cases caused serious loss. Districts where moisture was insufficient to cause early germination of the grain, thereby giving weeds a chance to grow, suffered most.

DISTRIBUTION OF SAMPLES OF GRAIN, FOREST TREES, TREE SEEDS, POTATOES, ETC.

During the months of March, April and May, the following distribution of products of the farm was made to applicants throughout the territories of Assiniboia, Alberta and Saskatchewan. The number of applications was largely in excess of the supply available for this purpose.

Samples of	Number.	Total.

EXHIBITIONS ATTENDED.

During the month of July the Winnipeg Industrial Exhibition in Winnipeg, Manitoba, was attended with an exhibit of products of the farm, consisting of grain in straw, grasses and threshed grain in bottles.

In August the united fair of the districts of Indian Head, Qu'Appelle Station and Fort Qu'Appelle, held at Qu'Appelle Station, was attended and an exhibit made similar to that at Winnipeg with the addition of vegetables from this farm and a very fine collection of fruit from the Experimental Farm for British Columbia at Agassiz.

In October an exhibit of vegetables and roots from Indian Head farm and a collection of apples from Agassiz was made at the Wapella Agricultural Society's fair held at Wapella, Assiniboia.

MEETINGS.

Meetings called by the North-west Dairymen's Association at Calgary and Olds, Innisfail, Red Deer, Lacombe, Wetaskiwin, Leduc, Edmonton and St. Albert, on the line of the Calgary and Edmonton Railway, were attended in March last. Except at Calgary the meetings were well attended. The work carried on on the Experimental Farms, the best methods of working land to meet climatic conditions, and to produce feed for dairy cattle were the principal topics referred to by myself.

The North-west Dairymen's Association delegates (Mr. Hopkins, president, Mr. Watson, vice-president, and Mr. Trant, secretary, spoke on dairy work exclusively.

VISITORS.

Visitors to the farm were more numerous during the past summer than ever before. The press excursion from Wisconsin and Minnesota made a short visit to the farm on their return from British Columbia. A large excursion from Moosejaw and points east to Qu'Appelle Station spent a day on the farm. With the farmers from this district and citizens of Indian Head, the visitors that day numbered nearly 1,500 people.

CORRESPONDENCE.

During the twelve months ending October 31, 1898, 4,702 letters were received, and 5,075 letters mailed from this office. In letters received, reports on grain and other samples are not counted, and in letters mailed, circulars of instruction *re* grain and other samples are not included.

I have the honour to be, sir,

Your obedient servant,

ANGUS MACKAY,

Superintendent.

EXPERIMENTAL FARM FOR BRITISH COLUMBIA

REPORT OF THOMAS A. SHARPE, SUPERINTENDENT.

AGASSIZ, B.C., 30th November, 1898.

To DR. WM. SAUNDERS,
Director, Dominion Experimental Farms,
Ottawa.

SIR,—I have the honour to submit herewith my report of progress made and work done for this, the tenth year, since work was commenced on this farm.

As in the season of 1896, so last year the coldest weather experienced during the winter was in November. The lowest temperature recorded here during last winter being 10 degrees above zero, the 28th of that month.

The winter was mild with a very light snowfall, and only a light rainfall. The spring, however, did not open very early, and April and May were so cold that growth was quite backward, and it was not until the middle of the latter month that really warm spring weather set in. June was rather unusually wet, insuring a heavy hay crop, but from early in July until after the most of the harvest was secured, the weather was very hot and dry. In some cases grain was ripened by the intense heat, too rapidly to fill properly, but the dry harvest weather cured it in fine condition, producing a bright, clean sample. The crop of hay has been very heavy throughout the province, and grain and roots of all kinds a good average. The land on the experimental farm having a light porous gravelly soil, suffered more from the drought than heavier soils did, lessening the yield of grain and roots in many cases, but on the whole the experimental farm crops are fairly good, as will be seen from the particulars herewith given.

HEDGES.

The sample hedges have continued to grow finely, and are attracting considerable attention. A good many visitors inspecting them with a view to choosing one for their own grounds.

FOREST TREE PLANTATIONS.

The forest tree plantations are making very strong and healthy growth in the cleared land on the level, and many of those planted on the mountain are making considerable progress.

ORNAMENTAL TREES AND SHRUBS.

These trees and shrubs have, with scarcely an exception, continued to make satisfactory growth. Some of the shrubs began to bloom in March, and the roses, Japanese hydrangeas, and some of the spiræas are still in bloom.

NUT TREES.

The Spanish and Japanese chestnuts fruited this year, and some of the nuts were very fine. The walnuts have all made a strong growth, and the variety known as Juglans max cordiformis, a heart-shaped nut, produced a fair crop.

ALMONDS.

Both hard and soft shelled varieties bloomed, but only the hard shelled sort fruited.

FILBERTS.

The spring was unfavourable for this fruit. The male flowers developed early in March, and the pollen was wasted before many of the female blossoms were ready to receive it, and consequently but few of them were fertilized. Perhaps when the bushes get age this may be remedied.

DISTRIBUTION OF SAMPLES.

A considerable number of samples of seed grain, potatoes, tree seeds and small fruit plants have been distributed during the past year. The following is a list of what was sent out in this way:—

Wheat, 3-pound packages	43
Oats " "	61
Pease " "	47
Barley " "	29
Potatoes	137
Scions and cuttings	134
Small fruits	71
Tree seeds and nuts	67
	589

BEES.

The bees have done very well this year, and although one or two swarms went away, we have seven at present, each one apparently well provided with honey for the winter.

STOCK.

The cattle mentioned in my report for last year as having the red water have not recovered, although they have been treated under the directions of a veterinary surgeon. The disease appears to be intermittent, sometimes almost, or quite disappearing for a while.

The live stock on the farm at present consists of the following:—Six working horses, nineteen head of cattle, six sheep, six pigs and sixty fowls.

BUILDINGS.

No new buildings have been erected this year, but material is being got ready for a pig house which it is proposed to erect before spring.

FENCING.

About three-quarters of a mile of wire fence was put up on the west side of the farm, and that part is now enclosed and protected.

BREAKING.

About ten acres of new land have been broken up this year; a part of it has been under crop this season, and the remainder will be ready for use next spring.

General view of the Experimental Farm at Agassiz, British Columbia, from the mountain

EXPERIMENTS WITH OATS.

Sixty-six varieties of oats were tested under conditions as nearly similar as was possible. All the seed was treated with bluestone before sowing, and there was very little smut. A few samples were rusty, but in most cases the injury was not severe. White Russian, Mortgage Lifter and Olive are among those that suffered from rust last year. White Wonder, Victoria Prize and Abundance, the remainder of those rusted last year were not affected this year, the straw being clean and bright.

These were all sown on the 18th April. The soil was a sandy loam which had been in clover for two years previous. It was ploughed in September, 1897, when the third crop of clover was in bloom, and the sod well cut up with the disc-harrow. This was disc-harrowed again early in the spring, and a third time later, and harrowed with the smoothing-harrow before sowing. The clover turned under was the only manure this land has ever received. The size of the plots was one-twentieth of an acre each.

SEED OATS TREATED FOR SMUT.

Comparative tests of three varieties of seed oats were made, treated with different remedies for the prevention of smut.

The soil on which these tests were made was a warm sandy loam which had been in Indian corn in 1897. The land was broken up in 1895 and sown with pease that year. It was used for roots in 1896 and has not yet received any manure or fertilizer.

Lot No. 1 in each variety was soaked in Bordeaux Mixture for four hours. This mixture was made with 4 pounds of sulphate of copper and 4 pounds of lime to 40 gallons of water.

Lot No. 2 was soaked in a solution of formalin for two hours, composed of 3 ozs. of formalin to 10 imperial gallons of water.

Lot No. 3 was soaked for two hours in a solution of formalin consisting of 4½ ozs. of formalin to 10 imperial gallons of water.

Lot 4 consisted of seed from the same samples untreated.

All these were sown on the same day, on soil as nearly uniform as possible, at the rate of two and a half bushels per acre, and all the heads, both smutty and clean, on an average square yard were counted.

No. of Plot.	Name of Variety.	Name of Fungicide.	Date of Sowing.	Date of Ripening.	Length of Heads.	Length of Straw.	Per cent of Smutty Heads.	Per cent of Clean Heads.

EXPERIMENTS WITH BARLEY.

Forty-one varieties of barley were sown in test plots of one-twentieth of an acre each. Nineteen of these were two-rowed, and twenty-two six-rowed sorts. All were sown on 21st April, which was three days later than the barley plots were sown last year, and the date of ripening is in some cases ten days earlier than that of last year. This was owing to the very hot and dry weather experienced here during July and August, which hastened the ripening of all the grain crops and thereby lessened the yield. There was no rust on any of the barley plots.

The soil was a sandy loam and the previous crop was corn. This land was ploughed in the spring and harrowed with disc-harrow and smoothing-harrow before sowing. It has not received any fertilizer since it was broken up.

EXPERIMENTS WITH SPRING WHEAT.

Forty-four varieties of spring wheat were tested in 1898. They were sown on 15th April on plots of one-twentieth acre each, on a light clay loam which had produced a crop of barley in 1897 and pease following clover in 1896. The land was ploughed in April, 1898, and disc-harrowed and harrowed with the smoothing-harrow before sowing. This land received a light dressing of manure in the autumn of 1894. No fertilizer has been applied since.

The yield promised to be very good in the early summer, but the hot dry weather forced the ripening forward so rapidly that the heads did not fill out nor was the grain as plump as it should have been. There was no rust and only a very little smut in one or two varieties.

EXPERIMENTS WITH PEASE.

Forty-seven varieties of pease were sown on fairly uniform land. The soil was black loam. Early in July these plots promised an extra heavy yield, but the hot weather prevented the fullest development of the pod, by hastening the ripening. King, as in 1897, leads the list in yield. All were sown on same date, 14th April, and the size of the plots was one-twentieth of an acre each.

Plots 5 and 6 in each case had been given a dressing with stable manure in autumn of 1897, because part of the surface soil had been removed in taking out large stumps, and this was thoroughly worked into the soil with drag and spading harrow before the seed was sown. This explains why the yield was so much larger on these plots. There was no smut on any of these oat plots.

Plots 5 and 6 in both tests had been given a dressing of stable manure in fall of 1897. This had been thoroughly worked into the soil, and will account for the relatively heavy yield in those plots. There was no rust or smut on any of these plots.

PEASE—RESULTS OF EARLY, MEDIUM AND LATE SOWINGS.

The soil of these plots was a sandy loam, the previous crop was clover, which was a light crop on account of the inferior character of the soil. This was turned under in the autumn, and the land prepared for seed in the spring by disc-harrowing and harrowing with the smoothing-harrow. The size of the plots was one-twentieth acre each.

EXPERIMENTS WITH INDIAN CORN.

Twenty-five varieties of corn were tested. From the time the corn was planted until nearly the end of June the season was unfavourable for this crop, being cold and wet, and up to 1st July the corn had made very little growth. From that time forward until it was cut, the weather was more favourable and the growth was rapid, but the yields do not equal those of last year. The soil on which this corn was planted was sandy loam. The corn was grown in rows and hills 3 feet apart, and all the varieties were planted on the 17th May.

INDIAN CORN PLANTED AT DIFFERENT DISTANCES.

Three varieties of corn were chosen for this test and both were planted in drills or rows ranging at differences of six inches, from 2 feet up to 4.

The plants were thinned to six inches apart in the drill and to four plants in each hill and in each case the hills were the same distance apart each way.

Four rows were planted of each variety in each case, and the two centre rows were weighed for comparison.

It is worth noting that the corn was more matured and the stalks leafier in the drills and rows from 3½ feet and wider. All were planted on May 17 and cut for ensilage Sept. 23.

The yield per acre is reckoned from the product of 66 feet of the two centre rows:—

EXPERIMENTS WITH TURNIPS.

Eighteen varieties of turnips were tested this year and two sowings were made in each case. The land used for this test was a clay loam which has been cropped for a number of years and is uniform in character, and the seed having been all sown on the same day and all subsequent treatment the same, the test may be considered a fair one, as between varieties. The yield per acre has been calculated from the weight of roots obtained from two rows each 66 feet long.

EXPERIMENTS WITH MANGELS.

Sixteen varieties of mangels were tested and two sowings of each were made. The land was a clay loam and the previous crop was small fruits. The spring during seeding time was rather unfavorable and the seed did not germinate well, and in consequence the stand was uneven and the yield considerably lessened, but, as in previous years, the early sown seed gives the best returns.

EXPERIMENTS WITH CARROTS.

Eighteen varieties of carrots were tested this year. Two sowings of each were made, the first on 28th April and the second on 12th May. The soil was a sandy loam in good condition and fairly uniform in character. One or two varieties suffered somewhat from having been sown on spots where fir stumps had been, and the soil was not as good. The yield per acre has been calculated from two rows each 66 feet long.

EXPERIMENTS WITH SUGAR BEETS.

Six varieties of sugar beets were tested. The land was a clay loam, one of the oldest worked pieces on the farm and was fairly uniform in character and moderately rich. The yields per acre were satisfactory. These have been calculated from the weight of roots gathered from two rows each 66 feet long.

EXPERIMENTS WITH POTATOES.

One hundred and eleven varieties of potatoes were tested this year. The soil was a strong clay loam, and had been in pease last year, which was the first crop since two or three large fir stumps had been taken out of this area, it was scarcely uniform in quality, and this reduced the yield of those potatoes which happened to be planted in such spots.

The yield on the whole, however, was very fair, the quality excellent and the percentage of rotten tubers was very small. The marketable average is fairly high. All were planted on 13th May.

SUMMARY OF HAY AND FORAGE CROPS HARVESTED.

	Tons.	Cwt.
Clover hay cured	55	15
Clover put into silo	28	0
Corn " "	34	4
Turnips	32	0
Mangels	7	15
Carrots	13	0
Sugar beets	2	5

A considerable quantity of clover, both first and second crop, was cut and fed green to the horses and cattle.

EXPERIMENTS WITH FODDER CROPS.

Fodder corn was cut and fed green from 1st of October until last of December, the silo not being large enough to hold it all, owing to the quantity of clover put into it.

The following mixtures of grain were sown to be cut green for fodder purposes. The soil was a sandy loam. The size of the plots was one-twentieth acre each.

Name of Variety.	Date of Sowing.	Date of Cutting.	Yield. — Weight when cut.		Yield. — Weight when cured.		Remarks.
			Tons.	Lbs.	Tons.	Lbs.	
Mixture No. 1 (sown with one bushel each of pease, barley and oats)	May 2..	July 18..	9	60	4	430	Cut when oats were in late milk.
Mixture No. 2 (sown with one bushel each of pease, wheat and oats)	" 2..	" 18..	8	1,760	3	1,380	" "

These mixtures continue to give good satisfaction, and where hay land is short provide a first class substitute.

EXPERIMENTS WITH JAPANESE MILLET, SOJA BEANS AND HORSE BEANS.

JAPANESE MILLET.

The seed of this millet, also the seed used in the two following tests of Soja Beans and Horse Beans, was received early in the season from the Director with instructions for sowing. The chief object in view in these experiments was to gain information as to the relative usefulness of these plants as forage crops in this climate and the weight of the crop obtainable from each when sown in different ways.

The land on which the Japanese Millet, Soja Beans and Horse Beans, were sown was a warm sandy loam which had received a dressing of stable manure in the winter of 1896. Where the seed was sown in drills the soil was kept clean and mellow with the cultivator. The season during midsummer being very hot and dry, the cultivation was very advantageous to the plants sown in drills.

The size of the plots was one-twentieth acre each.

Five test plots of the Japanese Millet were sown on 27th April, four of them in drills at different distances apart and one broadcast. They were all cut on the 10th September.

The growth was strong and the stalks leafy, with heads ranging from 2½ to 7 inches in length.

As will be seen by the records the wide drills gave the heaviest yields, the growth in every respect being greater, but where the stalks grow so stout and woody unless the fodder was run through an ensilage cutter there would be considerable waste in feeding. Horses and cattle eat it readily, either freshly cut or cured as hay.

JAPANESE MILLET.

Name of Variety.	Length of Straw.	Character of Straw.	Length of Head.	Yield per acre. — Green.		Cured. — Yield per acre.		Remarks.
	Inches.		Inches.	Tons.	Lbs.	Tons.	Lbs.	
Plot 1, drills 9 inches apart	52—54	Very leafy	5—6	12	600	6	400	Cut when seed was in late milk.
" 2 " 12 "	52—54	"	5—6	12	1,200	6	900	" "
" 3 " 15 "	56—60	"	5—6	14		7	300	Stalks very stout.
" 4 " 18 "	58—62	"	5—7	16	800	8	700	"
" 5 broadcast	36—48	"	2—6	7	1,000	3	1,500	Stalks slender and short.

SOJA BEANS.

These were sown in drills at different distances apart. The growth was from 35 to 40 inches high, and the plants branched so freely and had so many leaves that by midsummer the drills were not apparent. The branches were well loaded with pods containing from two to four beans each. This crop requires a longer season to ripen the bean, but it makes a fine fodder for green feed, the cattle and horses preferring it to any other food. All of it was fed green as our silo was full and the weather was unfavourable for curing it.

SOJA BEANS.

Name of Variety.	Date of Sowing.	Date of Cutting.	Length of Straw.	Yield per acre.	Remarks.
			Inches.	Tons. Lbs.	
Plot 1, drills 2 feet apart	April 27..	Oct. 5.	30—40	6 800	Cut when beans were in a soft green state.
" 2 " 2½ "	" 27..	" 5..	35—40	5 1,800	" "
" 3 " 3 "	" 27..	" 5..	35—40	5 800	" "

HORSE BEANS.

Three plots of these beans were sown. The seed did not germinate well, and the stand was in consequence uneven and poor. The plants grew from 30 to 34 inches high and were fairly well podded, but the pods were short, averaging about three beans each. When cut some of the lower pods were ripe and the beans beginning to shell. Cut 19th September, and mixed with corn and put into silo or fed green.

Nomber of Plot.	Date of Sowing.	Date of Cutting.	Height of Plant.	Yield per acre.	Remarks.
			Inches.	Tons. Lbs.	
Plot 1, drills 2 feet apart	April 27..	Sept. 19..	30—34	3 600	Cut when lower pods were ripe.
" 2 " 2½ "	" 27..	" 19..	30—40	2 900	" "
" 3 " 3 "	" 27..	" 19..	30—40	2 300	" "

EXPERIMENTS WITH CLOVER SEED INOCULATED WITH NITRAGIN AND WITHOUT NITRAGIN.

The soil for these tests was a clay loam that had been used as a nursery for some years, but which had received no manure since 1892, when it was given a light dressing of stable manure. This land was ploughed early in the spring of 1898 and sown with a mixture of pease and oats which had made a fair growth, when turned under for the clover tests. Four plots of one-twentieth of an acre each were laid out, and two of these sown with the clover seed which had been treated, one at the rate of 10 pounds per acre, and the other at the rate of 7 pounds per acre. The other two plots were sown

View on the Experimental Farm at Agassiz, British Columbia, showing part of Arboretum and residence of Superintendent.

with untreated seed at the same rate. The heaviest seeding gave the thickest stand, but apart from that there seemed to be no perceptible difference in the growth at the end of the season.

POULTRY.

There are four breeds of poultry on the farm—Light Brahmas, White Wyandottes, Black Minorcas, and White Leghorns. These fowls have a comfortable house, and, excepting those which are kept in breeding pens, are allowed to run at large and are regularly fed and cared for. They were not forced in any way either for laying or fattening.

The Black Minorcas are the best layers, and their eggs are large.

The Light Brahmas are the best for the table and second as layers. A pair of Brahma cockerels weighed 9¼ pounds at four months old.

The White Wyandottes are very nearly equal to the Light Brahmas as broilers. A pair of White Wyandotte cockerels weighed 8 pounds 3 ounces at four months old; they have not been as good layers here as the Light Brahmas.

The White Leghorns are good layers, but their eggs are small and their bodies so small that they are of little value for the table.

LARGE FRUITS.

APPLES.

This has been an off year for apples in old orchards or where trees have been bearing continuously for several years. Of winter apples, Salome, Scotts Winter, Baldwin, Ben Davis and Sutton Beauty were the only varieties amongst the old trees that bore a fairly good crop.

In the newer plantations and on the benches the crop has been a fairly good one. The forest tent caterpillar was very plentiful, and where orchards were not promptly sprayed they did considerable damage. A large number of the Russian varieties of apples fruited this year. The trees in almost every case are strong growers and early bearers, but nearly all of them are summer or early autumn apples. The trees on the benches have made a very satisfactory growth, and many of them had some fruit, but unfortunately a good deal of this was destroyed by bears which were very numerous this year, four having been shot in our orchards and others seen.

The following extracts are from notes taken, describing some of the best of those varieties which fruited for the first time this year:—

Red Juneating.—Tree a moderate grower and fairly productive. Fruit small to medium in size, conical. Skin greenish yellow, nearly covered with red. Flesh white, crisp, and juicy, acid. Ripe last of July.

Arkad Solovieff.—Tree a strong, vigorous grower. Fruit above medium size of an irregular, conical shape. Skin waxen yellow. Flesh white, juicy, nearly sweet, perfumed. Ripe last of July.

Skrosnina Grell.—Tree vigorous and productive. Fruit of medium size, roundish flat. Skin yellow with a bronze cheek. Flesh white, crisp, juicy, mild sub acid. Season, last of July.

Rosy Voronesh, 1277.—Tree a vigorous grower. Fruit above medium size, oblong conical. Skin yellow streaked and splashed with red. Flesh white, crisp, juicy, pleasant, a little coarse. Season, early August.

Rosy Repka.—Tree vigorous and productive. Fruit above medium size, conical. Skin green, striped and splashed with red and with a whitish bloom. Flesh coarse, juicy, sprightly, flavour good. Season, August.

Pewaukee Russet.—Tree a very vigorous grower, Fruit flattish, conical. Skin russet green, nearly covered with splashes of red in two shades. Flesh white, juicy, coarse, a pleasant, mild, acid. Season, August.

White Cardinal.—Tree a moderate grower, productive. Fruit large, flattish, tapering to the eye. Skin of a clear yellow colour. Flesh coarse, crisp, mildly acid. Season, August.

Newton.—Tree a vigorous grower. Fruit of medium size, slightly conical. Skin green, nearly covered with red. Flesh white, crisp, acid. Season, August.

Excelsior.—Tree a strong, vigorous grower and productive. Fruit of medium size, nearly globular. Skin yellow with a bright red cheek. Flesh crisp, juicy, white, mildly acid and pleasant. Season, August.

Repolovka 1 M.—Tree a vigorous grower. Fruit of medium size, globular. Skin white with a reddish cheek. Flesh white, juicy, firm and of a brisk acid. Season, August.

Golden Reinette.—Tree vigorous and productive. Fruit round, flat and of medium size. Flesh white, coarse, juicy, a mild acid. Season, August.

Koursk Anis.—Tree a strong grower. Fruit of medium size, flat. Skin green, nearly covered with dark purple. Flesh white, juicy and pleasantly acid. Season, August.

Arabka.—Tree a vigorous grower. Fruit of medium size, oblong conical. Skin green, nearly covered with dull red. Flesh white, moderately juicy, sweet, pleasant. Season, August.

Flat Voronesh.—Tree a vigorous grower and productive. Fruit very similar to the Duchess, but considerably larger. Season, August.

William's Favourite.—Tree a vigorous grower. Fruit above medium in size, conical. Skin green, splashed and streaked with pale and dark red. Flesh white, crisp, pleasant and mildly acid. Season, August.

Ruby Gem.—Tree a moderate grower. Fruit of medium size, globular. Skin green, nearly covered with dull red and sprinkled with small white dots. Flesh white, fine, crisp, juicy, of a mild and pleasant acid. Season, August.

Porter.—Tree vigorous and productive. Fruit above medium size, oblong, yellow. Flesh white, tender and of fine flavour. Season, August.

Kara Synap A.—Tree a strong and vigorous grower. Fruit of medium size, flat, conical. Skin green, freely splashed with red. Flesh yellowish, crisp, juicy, rather coarse but pleasant. Season, August.

Paperovka.—Tree vigorous. Fruit above medium size, conical. Skin yellowish white. Flesh white, dry, coarse and granular. Season, August.

Gracie.—Tree vigorous and productive. Fruit large, flattish, conical. Skin whitish green. Flesh white, coarse and mildly acid. Season, August.

Blushed Calville.—Tree a vigorous grower. Fruit above medium in size, flattish Skin yellow. Flesh tender, white, juicy, pleasant. Season, August.

Red Streak.—Tree a vigorous grower. Fruit large, similar in appearance and quality to Alexander, but earlier. Season, August.

Persian Bogdanoff.—Tree a vigorous grower. Fruit of medium size, oblong, conical. Skin green, nearly covered with dull red. Flesh white, moderately juicy, sweet and pleasant. Season, August.

Pointed Pipka.—Tree a vigorous grower. Fruit above medium in size, oblong, conical. Skin whitish yellow, nearly covered with streaks and splashes of bright red. Flesh coarse, juicy, crisp and mildly acid. Season, August.

Little Hat.—Tree a vigorous grower. Fruit large, oblong conical. Skin green, splashed and striped with bright red. Flesh yellow, a little soft, juicy, acid. Season, August.

Anisovka.—Tree a vigorous grower and productive. Fruit very similar to Duchess in quality and season, but larger. Season, August.

Orel.—Tree a vigorous grower. Fruit of the Alexander type, large, handsome, and a good cooking apple. Season, August.

Avenarius.—Tree a vigorous grower. Fruit of medium size, nearly round. Skin yellowish green, nearly covered with streaks and spots of light red. Flesh white, not juicy, mildly acid. Season, August.

Headly.—Tree a vigorous grower and productive. Fruit very similar to Duchess, but nearly a month later. Season, last of August and first of September.

Green Stripe.—Tree a strong grower. Fruit large, oblong, conical. Skin greenish white, with red stripes and sprinkled with white dots. Flesh white, firm, juicy and pleasantly acid. Season, August.

Mank's Codlin.—Tree an early and free bearer. Fruit of medium size, oblong, conical. Skin yellow, with a warm blush on the sunny side. Flesh yellowish white, crisp, juicy, and pleasantly acid. Season, August and September.

Deane's Codlin.—Tree a vigorous grower and productive. Fruit large, oblong, slightly conical. Skin yellow. Flesh white, juicy, and of a pleasant character. Season, August and September.

Grandmother.—Tree a vigorous grower. Fruit above medium in size, flattish, conical. Skin greenish white, streaked and splashed with light red. Flesh rather dry, granular and sweet. Season, autumn.

Baraboo.—Tree a vigorous grower. Fruit of medium size, flat. Skin russet white, with a light blush on the sunny side. Flesh white, juicy, acid. Season, autumn.

Rambour Reinette.—Tree a vigorous grower. Fruit large, irregular, ribbed, conical. Skin yellow, with a little red on the sunny side. Flesh white, coarse, juicy, acid. Season, autumn.

Summer Spice.—Tree a vigorous grower and an early bearer. Fruit of medium size, oblong, tapering to the eye. Skin yellow. Flesh white, not juicy, but mildly acid, pleasant. Season, autumn.

Quaker Beauty.—Tree a vigorous grower. Fruit above medium size, flattish, conical. Skin russet green, with a warm blush. Flesh white, not juicy, but mildly acid. Season, autumn.

Russian Preserve.—Tree a vigorous grower and productive. Fruit of medium size, round and flattened. Skin greenish white. Flesh dry, tough, white, sweet, and of poor flavour. Season, September.

Long Arcade.—Tree a vigorous grower. Fruit large, irregular, conical. Skin green, nearly covered with red, and with many small white dots. Flesh white, juicy and pleasant. Season, September.

Early Ripe.—Tree a moderate grower. Fruit above medium size, oblate. Skin green, with a bronze red cheek. Flesh white, crisp, juicy, mildly acid and pleasant. Season, autumn.

Lowell.—Tree a vigorous grower and productive. Fruit large, oblong. Skin yellow, oily. Flesh yellowish white, crisp, tender and of fine flavour. Season, September and October.

Borsdorf.—Tree a vigorous grower and productive. Fruit above medium size, oblong, tapering to the eye. Skin green, streaked with dull red. Flesh white, mildly acid and juicy. Season, September.

Western Beauty.—Tree a vigorous and spreading grower. Fruit large, flattish, globular. Skin greenish white, with splashes and dots of red. Flesh white, mildly acid, juicy, crisp and pleasant. Season, September.

Day.—Tree a vigorous grower. Fruit large, oblate. Skin green, with numerous small whitish dots and a little red on the sunny side. Flesh, yellowish white, crisp, juicy and pleasant. Season, September.

Flora Belle.—Tree a vigorous grower and productive. Fruit large, oblong, conical. Skin rich yellow, with small patches of russet and small dots. Flesh yellowish, tender, crisp, subacid, pleasant. Season, autumn.

Fall Wine.—Tree a moderate grower. Fruit large, conical. Skin green, with a small dull red cheek and sprinkled with whitish dots. Flesh yellowish, juicy, tender, mildly acid, and of fine flavour. Season, autumn.

Gremuck.—Tree a very vigorous grower. Fruit very large, conical. Skin green, with a few stripes of red. Flesh white, coarse, acid; quality poor. Season, autumn.

Royal Table.—Tree a vigorous grower and productive. Fruit of medium size, globular. Skin green, with a blush and sprinkled with white dots. Flesh white, crisp, juicy and of a pleasant flavour. Season, October and November.

Mother.—Tree a vigorous grower and productive. Fruit above medium size, oblong, tapering a little. Skin green and nearly covered with bright red and many small white dots. Flesh yellowish white, crisp, tender, juicy, a mild subacid; quality very good. Season, October and November.

Haskell's Sweet.—Tree a moderate grower. Fruit above medium size, oblate. Skin green, with a dull blush. Flesh yellowish white, fine-grained, tender, juicy and sweet. Season, autumn.

Simbirsk No. 11.—Tree a strong grower. Fruit of medium size, flat, conical. Skin green, with a reddish blush. Flesh white, firm, juicy, subacid. Season, autumn.

Tyler's Kernel.—Tree a moderate grower. Fruit large, oblong, conical. Skin green, nearly covered with dull red, and sprinkled with white dots. Flesh yellowish white, firm, juicy and mildly acid. Season, autumn.

Early Strawberry.—Tree a moderate grower. Fruit small to medium in size, oblate. Skin yellow, with a russet cheek and a few streaks of dull red. Flesh white, firm, juicy and pleasantly acid. Season, autumn.

Pumpkin Sweet.—Tree a strong grower. Fruit large, roundish. Skin light green, with white dots and streaks. Flesh sweet, white, not juicy. Season, autumn.

Gideon's No. 20.—Tree a vigorous grower and productive. Fruit of medium size, conical. Skin greenish yellow. Flesh white, firm, crisp, juicy. Season, autumn.

Peasegood's Nonsuch.—Tree a spreading but moderate grower. Fruit large, globular. Skin whitish green, with a pale red blush and many small whitish dots. Flesh white, juicy, firm, mildly acid and pleasant. Season, autumn.

Wyken Pippin.—Tree a medium grower. Fruit below medium in size, oblate. Skin greenish yellow, sprinkled with gray dots. Flesh white, firm, juicy and pleasant. Season, autumn.

Margil.—Tree a moderate grower. Fruit of medium size, roundish oblate. Skin green, nearly covered with red. Flesh yellow, firm, juicy, with an aromatic pleasant flavour. Season, autumn.

Arabskoe.—Tree a vigorous grower and productive. Fruit large to very large, ribbed, conical. Skin green, nearly covered with smoky red, and sprinkled with small white dots. Flesh firm, white, coarse, juicy, and pleasantly acid. Season, late autumn.

Bismarck.—Tree a vigorous grower and productive. Fruit above medium in size, conical. Skin green, nearly covered with red. Flesh rather coarse, white, juicy, mildly acid. Season, November and December.

Nonpareil.—Tree a moderate grower. Fruit small, globular, flattened. Skin greenish yellow, nearly covered with russet. Flesh white, firm, moderately juicy and of pleasant flavour. Season, December.

Arabka Winter.—Tree a strong grower and productive. Fruit large to very large. Skin green, nearly covered with dull purple. Flesh white, firm, mildly acid and juicy. Season, late autumn.

Red Winter Calville.—Tree a moderate grower. Fruit large, oblong, conical. Skin green, with a reddish bronze cheek. Season, winter.

White Calville.—Tree a moderate grower. Fruit above medium size, oblong, ribbed. Skin greenish white. Season, winter.

Pomme d'Eve.—Tree a slow grower. Fruit under medium size, oblong, globular. Skin green, with a russet bronze cheek. Season, winter.

Red Winter Pearmain.—Tree a medium grower and productive. Fruit of medium size, oblong, conical. Skin greenish yellow, nearly covered with red and sprinkled with light dots. Season, winter.

Golden Harvey.—Tree a moderate grower. Fruit small, oblong, round. Skin rough, russet, with a dull red cheek. Flesh yellowish, firm, juicy, spicy, rich, and of pleasant flavour. Season, winter.

Golden Nonpareil.—Tree a moderate grower. Fruit small, roundish, of a golden yellow colour with a russet blush on the sunny side. Flesh juicy, crisp and acid. Season, winter.

Ingram.—Tree a vigorous grower. Fruit small, roundish, flattened. Skin green, with small stripes and splashes of red, and many small whitish dots. Season, winter.

Arkansas Beauty.—Tree a vigorous grower and productive. Fruit of medium size, globular. Skin green, with a bronze cheek and many small white dots. Season, winter.

Red Winter Pearmain.—Tree a moderate grower. Fruit of medium size, roundish, oblong, conical. Skin yellowish white, nearly covered with dull red, and freely sprinkled with light dots. Season, winter.

Reinette d'Angleterre.—Tree a moderate grower. Fruit above medium in size, roundish, conical. Skin yellow, with splashes of light red. Season, winter.

Bradford's Best.—Tree a vigorous grower. Fruit small to medium in size, round, flat, green, with a reddish cheek and many light dots. Very liable to black scab. Season, winter.

Jacob Sweet.—Tree a moderate grower. Fruit large, oblong, globular, somewhat conical. Skin green, with a brown red blush. Season, winter.

Danver's Winter.—Tree a vigorous grower and productive. Fruit above medium size, oblong, conical. Skin smooth, yellow. Season, winter.

De Chataignier.—Tree a moderate grower. Fruit small to medium in size, globular. Skin greenish yellow, and speckled with white dots. Season, winter.

Pyle's Red Winter.—Tree vigorous. Fruit of medium size, roundish, oblong, conical. Skin green, nearly covered with red, and sprinkled with whitish dots. Season, winter.

Indian.—Tree a vigorous grower and productive. Fruit above medium size, oblong, conical. Skin yellow, splashed and streaked over nearly the whole surface with two shades of red, and many small whitish dots. Flesh yellowish, fine grained, tender, crisp, juicy, mildly subacid and of good quality. Season, winter.

Dickinson.—Tree a vigorous grower and productive. Fruit above medium size, oblong, inclining to conical. Skin yellowish, with red nearly covering the surface, and freely sprinkled with whitish dots. Season, winter.

Parker's Pippin.—Tree a vigorous grower and productive. Fruit medium to large, round, conical. Skin yellow, with a considerable quantity of russet. Season, winter.

Taffet Winter.—Tree a strong grower. Fruit small to medium, oblate. Skin greenish yellow, with a blush. Season, winter.

Burckhardt's Reinette.—Tree a vigorous grower and productive. Fruit of medium size, round, flattish. Skin russet yellow. Season, winter.

Green Reinette.—Tree a vigorous grower. Fruit of medium size, roundish, flattened. Skin yellowish green, with a little russet. Season, winter.

Round Borsdorf.—Tree a vigorous grower. Fruit small, round, flat. Skin greenish yellow, with a bronze cheek. Season, winter.

Queen Olga.—Tree a vigorous grower and an early bearer. Fruit of medium size, long, oblong, tapering to the eye. Skin yellowish green, with a faint blush and a few white dots. Season, winter.

Cantil Sinap.—Tree a vigorous grower. Fruit oblong and of medium size, tapering to the eye. Skin yellowish green, with russet and splashes of pale red on the sunny side. Season, winter.

Doux d'Argent.—Tree a moderate grower. Fruit of medium size, round, flattened. Skin yellowish green, with many white dots. Flesh firm, juicy, mildly acid and of a fine and pleasant flavour. Season, winter.

Red Queen.—Tree a vigorous grower. Fruit of medium size, oblong, conical. Skin greenish yellow, with a warm blush. Season, winter.

North Carolina Limbertwig.—Tree a vigorous grower. Fruit of medium size, roundish, conical. Skin yellowish green, with a russet and dull red cheek. Season, winter.

Iowa Blush.—Fruited for the first time in 1897, and then classed as a winter apple. Proved to be a very fine keeper, keeping crisp and full flavoured until May.

Scarlet Cranberry.—Fruit small, flat and roundish, of fair quality, keeps with care until a year old, a plate each of the growth of 1897 and 1898 being shown in the Experimental Farm exhibit this year.

Carthouse.—Another apple reported on for the first time in 1897, keeps until the last of March in excellent condition, with a very small percentage of loss.

CRAB APPLES.

Red Siberian.—Tree a vigorous but slender grower. Fruit of medium size, flattish. Skin smooth, yellow, covered with bright red. Season, August.

Ogilvie's Crab.—Tree a vigorous grower and productive. Fruit above medium size, oblong, globular. Skin a warm yellow, with a pink blush. Season, August.

No. 3 Sweet.—Tree a vigorous grower and productive. Fruit of medium size, oval. Skin greenish white, with red in two shades covering nearly the whole surface, and a bluish bloom. Season, August.

Paul's Imperial.—Tree a vigorous grower and productive. Fruit above medium size, round, flattish. Colour white, nearly covered with purple, with a bluish white bloom. Season, August.

Peach.—Tree a vigorous grower and productive. Fruit of medium size, oblong. Skin green, with a handsome blush. Season, August.

Lady Elgin.—Tree a moderate grower. Fruit small to medium in size, oblong, flattened. Skin yellow, nearly covered with a pale dull red. Season, September.

Chickasaw.—Tree a vigorous grower. Fruit small, roundish globular. Skin green, nearly covered with a dull reddish tint. Season, September.

Alaska.—Tree a vigorous grower and productive. Fruit above medium in size, oblong, conical. Skin greenish white, splashed with dull pale red on the sunny side. Season, October.

PEARS.

Very few of the older pear trees bore fruit this year, and in those cases where they did bear, the crop was small and inferior in quality. The following varieties fruited for the first time :—

Beurre Jacob.—Tree a strong spreading grower and an early bearer. Fruit of medium size, oblong, pyriform. Skin warm yellow, with a red cheek and freely sprinkled with grayish dots. Flesh white, rather coarse, granular, not juicy, has a tendency to rot at the core. Season, August.

Beurre Giffard.—Tree a moderate grower. Fruit of medium size, pyriform, taperring to the stem. Skin greenish yellow, with patches of russet. Flesh white, tender, granular, medium juicy, sweet, quality good. Season, August.

Early Madelaine.—Tree an upright and vigorous grower. Fruit of medium size, obovate pyriform. Skin yellowish green, with russet specks. Flesh white, juicy, but not high flavoured. This pear seems very liable to crack.

Goodale.—Tree a vigorous grower but slow in coming into bearing. Fruit above medium size, oblong, obtuse pyriform. Skin light yellow with a blush on the sunny side and small patches of russet. Flesh white, juicy, yellowish, rather coarse, and gritty at the core. Season, September.

Colmar d'Été.—Tree a moderately vigorous grower. Fruit of medium size, roundish pyriform. Skin greenish yellow, freely sprinkled with grayish dots and occasionally a slight blush in the sun. Flesh white, coarse, not very good, often rots at core. Season, September.

St. Swithin.—Tree a vigorous grower. Fruit below medium size, obovate pyriform. Skin green, with a few russet dots. Flesh white, juicy, buttery and of fine flavour. Season, August and September.

Van Mons.—Tree a moderate grower. Fruit of medium size, obovate pyriform. Skin greenish yellow, with patches of russet and many brown dots. Flesh white, juicy, melting sweet and pleasant. Season, September.

Smith's Hybrid.—Tree a vigorous and upright grower. Fruit, large very similar to LeConte, but superior in quality to that variety. Season, August and September.

Duhamel du Monceau.—Tree a vigorous grower. Fruit of medium size, roundish pyriform. Skin pale greenish yellow, with a brownish red cheek in the sun, and sprinkled with russet dots. Flesh whitish, fine grained, sweet, juicy and of pleasant flavour. Season, October.

Japan Golden Russet.—Tree a vigorous and upright grower. Fruit small to medium in size, oval, stem long. Skin greenish russet, freely sprinkled with grayish dots. Flesh white, juicy, firm. Flavour peculiar but not very pleasant. Season, October and November.

Directeur Alphande.—Tree a vigorous grower. Fruit large, obtuse pyriform. Skin green, freely sprinkled with gray dots. Season, winter.

Emile d'Heyst.—Tree a vigorous grower. Fruit large, oblong pyriform. Skin yellow, with a bronze orange cheek in the sun, and many russet dots. Flesh yellowish white, fine grained, sweet, juicy and of a pleasant flavour. Season, November.

Dr. Jules Guyot, Rivers Princess and Durondeau, of the newer pears are the most productive varieties thus far tested for summer and autumn, and Knight's Monarch for winter.

PLUMS.

The European varieties of plums appear to find a congenial soil and climate in British Columbia. No other fruit on the Experimental Farm is so persistent and regular in producing large crops.

The Japanese plums bloom very profusely, but what fruit sets begins falling as soon as set, and very little is left by the time it is full grown.

The American plum trees bloom freely, but the blossoms fall, a few pounds being the best crop yet obtained from any of these varieties, while some of the European sorts of the same age have produced from one to three hundred pounds of marketable fruit.

View of part of a Washington Plum tree in fruit, growing on the Experimental Farm at Agassiz, British Columbia. [401]

The following varieties fruited for the first time this year :—

Richland.—Tree a vigorous grower. Fruit below medium in size. Skin greenish purple. Flesh greenish, juicy and of fine flavour. Ripe early in August.

Excelsior.—Tree a medium grower. Fruit small, round. Skin nearly scarlet. Flesh reddish, juicy and of fine flavour. Ripe early in August.

Monsieur June.—Tree a moderate grower. Fruit of medium size, roundish. Skin yellow, with a little red near the stem. Flesh yellow, juicy, melting, sweet and of fine flavour. Season, August.

Orel, No. 19.—Tree a vigorous grower. Fruit small to medium, oblong, globular. Skin purple, with a bluish bloom. Flesh greenish, juicy and of pleasant flavour. Season, August.

Yunkin Golden.—Tree a strong grower. Fruit below medium size, globular. Skin a rich reddish golden colour. Flesh yellow, juicy and of a rich, pleasant flavour. Season, Ausust.

Wangenheim.—Tree a medium grower. Fruit of medium size, oblong, oval. Skin deep purple, with a blue bloom. Flesh greenish, juicy, sweet and of a rich flavour. Season, August.

Luscombe's Nonsuch.—Tree a vigorous grower. Fruit above medium size, globular. Skin greenish yellow, with orange streaks. Flesh yellow, sweet but not very juicy. Season, August.

Huling's Superb.—Tree a strong grower. Fruit above medium size, roundish, oval, one side enlarged. Skin greenish yellow, with a light bloom. Flesh yellow, juicy and of a pleasant flavour. Season, August.

Reine Claude Rouge.—Tree a moderate grower. Fruit of medium size, round. Skin, reddish purple, with a thin bloom. Flesh, greenish, juicy, with a pleasant flavour. Season, last of August.

Reine Claude Vert.—Tree a moderate grower. Fruit small, roundish. Skin deep purple with a heavy blue bloom. Flesh, greenish, juicy with a pleasant flavour. Season, August.

Reine Claude Transparent.—Tree a moderate grower. Fruit of medium size, roundish with one side enlarged. Skin light yellow with reddish streaks. Flesh yellow, juicy, tender, sweet and of very fine flavour. Season, August.

President Courcelles.—Tree a moderate grower. Fruit below medium size, heart-shaped. Skin deep purple with a blue bloom. Flesh greenish, sweet, juicy, with a pleasant flavour. Season, August.

Pershore.—Tree a strong grower and productive. Fruit of medium size, pear shaped. Skin golden yellow. Flesh yellow, lacking in juiciness, slightly acid. Season, August.

Ickworth's Imperatrice.—Tree a medium grower. Fruit of medium size, roundish. Skin, purple with lighter streaks. Flesh greenish yellow, sweet, juicy and rich. Season, August.

Blubenthal Damson.—Tree a vigorous grower and early producer. Fruit one of the largest of the damsons, heart-shaped. Skin deep purple with a heavy blue bloom. Flesh green, juicy and sprightly. Season, August.

Cochet Pere.—Tree a vigorous grower and an early bearer. Fruit above medium in size, oblong globular. Skin golden yellow. Flesh yellow, sweet, not juicy, not of high quality. Season, August.

Des Bejonnières.—Tree vigorous and an early bearer. Fruit of medium size, globular. Skin yellow. Flesh yellow, juicy, sweet, and of fine quality. Season, August.

Late Transparent.—Tree a vigorous grower. Fruit of medium size, round. Skin greenish yellow, with a reddish cheek in the sun. Flesh yellowish, juicy, sweet and of fine flavour. Season, August.

Petite Mirabelle.—Tree a slow grower. Fruit very small, round. Skin whitish yellow, with small red dots, and a whitish bloom, Flesh yellowish, sweet, juicy and very pleasant, a free stone variety. Ripe, 20th August.

Bryanston's Gage.—Tree a strong grower. Fruit of medium size, oval. Skin yellow with a dull red cheek. Flesh yellow, coarse, juicy, sweet and of pleasant flavour. Season, late August.

Giant Prune.—Tree a strong and vigorous grower and early bearer. Fruit large, oval. Skin purple. Flesh firm, sweet, juicy and pleasant. Season, late August.

Bazalieza's Prune.—Tree a vigorous grower and productive. Fruit above medium size, oblong, oval. Skin reddish purple, with a whitish bloom. Flesh greenish, sweet, moderately juicy and of fine quality. Season, August.

CHERRIES.

The cherry crop has been a light one this year. Some of the sweet varieties bore fairly well, but the birds are fond of them, and before the crop was fit to pick, the birds had taken the most of it.

Quite a number of the Russian cherries fruited again this year, and as they are all more or less acid, they are not touched by birds. Some of them are of fair size, excellent for canning, and when fully ripe quite pleasant for table use, and as the trees begin to bear when young and are fairly productive, they are well worth planting both for home use and market.

The following are, so far as tested, the best of this class : Straus Wiechsel, Gruner Glass, Shadow Amarelle and Kings Morello. The following fruited this year for the first time :—

Cleveland.—Tree a strong grower. Fruit large, obtuse, heart shaped. Skin yellowish white, with a warm blush in the sun. Flesh yellowish, firm, juicy, sweet, and of pleasant flavour. Season, middle of June.

Glaskirsch Doppelte.—Tree a medium grower. Fruit under medium size, round. Skin light red. Flesh yellowish, juicy, sprightly, with a pleasant flavour. Season, last of June.

Orel No. 24.—Tree a medium grower. Fruit of medium size. Skin bright red. Flesh yellowish white, juicy, tender, mildly subacid, and of pleasant flavour. Season, last of June.

Kings Morello.—Tree a medium grower. Fruit of medium size, round. Skin pale red. Flesh yellowish white, juicy, tender, sprightly and refreshing. Season, early July.

Griotte d'Ostheim.—Tree a moderate grower. Fruit under medium size, nearly globular. Skin a reddish wine colour. Flesh firm, juicy, sprightly, and of fine quality. Season, early July.

Carnation.—Tree a vigorous grower. Fruit above medium size, round. Skin bright red. Flesh juicy, sprightly, nearly sweet, refreshing. Season, early July.

Centennial.—Tree a vigorous grower. Fruit large, round, deep red. Flesh juicy, tender, sweet and of very fine flavour. Season, July.

Rocky Mt. Cherries.—These bushes have made a strong growth this year, but none of them have fruited.

PEACHES.

The peach crop on the level land this year was almost an entire failure. The curl leaf was very prevalent, nearly every tree being seriously affected with it. The trees were sprayed with Bordeaux mixture, both before leafing out and several times after, but the spraying did not appear to be effective. In the valley the Amsden, Alexander, Early Canada and Mountain Rose had each a few peaches, and on the bench the Amsden and Hilborn had very good crops, and the curl leaf did not affect the foliage there, in fact it has never injured the foliage on either peach or nectarine trees on the benches over 300 feet above the valley.

APRICOTS.

The apricot, like the peach and nectarine blooms so early that the weather is very likely to be cool and wet, and the trees although blossoming profusely set very little fruit.

The European apricot trees grow vigorously for a few years and then the large limbs begin to die and the trees go to pieces.

The Russian varieties are hardier in the timber, and longer lived than the tenderer European sorts, but they do not fruit well. Our trees although large and vigorous growers, and blooming freely every year have not yet averaged 2 lbs. of fruit per tree per annum.

NECTARINES.

Only one of the nectarine trees fruited this year. The Spenser bore about 1 doz. nectarines, which seems to be about an average crop. In sheltered locations or on a wall, peaches, apricots or nectarines would perhaps fruit fairly well here, but in the open orchard they are not profitable.

MULBERRIES.

All the mulbery trees fruited freely again this season.

The fruit began ripening early in July, and continued in season until 1st September. Fruit juicy, sweet and pleasant, but drops from the tree when fully ripe.

MEDLARS.

The trees have made a strong growth, and have all produced a full crop. The Nottingham is perhaps the best, being a little the smoothest and evenest in size, but all the varieties are free producers, and the quality is nearly the same in them all.

SMALL FRUITS.

GOOSEBERRIES.

The gooseberries were sprayed with the lime sulphur and salt mixture during the winter, and with Bordeaux mixture before leafing out, and the sprayings with Bord eaux mixture were repeated several times during the spring and summer, but the results were not satisfactory. None of the European varieties escaped the mildew, except a few bushes planted on one of the benches, and these, although they have never been sprayed, have never shown the disease either on leaf or fruit.

GRAPES.

The season has been unusually free from fogs and smoke, and many more varieties of grapes ripened than has been the case heretofore, over sixty varieties were exhibited at the New Westminster exhibition. Here again there is a decided gain in getting on elevated lands, grapes on the bench ripened fully two weeks earlier than the same varieties on the level.

RED AND WHITE CURRANTS.

The season has been a good one for red and white currants and for all varieties of small fruits, there was sufficient rain early in the summer and in the autumn they had plenty of bright sunshine the result being in most cases a good crop of excellent fruit. The following extracts are from the notes taken of the different varieties.

RED AND WHITE CURRANTS.

Name.	Date of Ripening.	Growth of Plant.	Size of Fruit.	Quality.	Productiveness.
Moore's Ruby (red.)	June 23	Vigorous ...	Large	Cluster, medium in length, fairly well filled, a little acid, of good flavour.	Productive.
Versailles (red).	" 23	" ...	"	Cluster, medium in length, open, of good flavour.	"
Fay's Prolific (red.)	" 23	" ...	"	Cluster, medium in length, of good flavour.	"
Red Langtraubige.	" 25	" ...	Medium	Cluster, long, and well filled, of good flavour.	Moderately productive.
Admirable (red)	" 25	" ...	Above medium	Cluster, long and full, mild, of pleasant flavour.	Fairly productive.
Victoria (red)..	" 25	" ...	Medium......	Cluster, long, fairly well filled, sweet, of good flavour.	Productive.
Eyatt's Nova (red.)	" 26	" ...	Above medium	Cluster, long, not very full, sweet, and of good flavour.	Moderately productive.
English Red....	" 26	" ...	"	Cluster, long and full, of very fine flavour.	Fairly productive.
Brandenburger (white.)	" 26	" ...	Large	Cluster, medium in length, fairly full, sweet, of good flavour.	Moderately productive.
White Kaiser...	" 26	" ...	Medium	Cluster, long, but not well filled, seeds yellowish red, of gocd flavour.	"
Raby Castle (red)	" 26	" ...	"	Cluster, medium in length, rather open, of good flavour.	Productive.
London Red....	" 26	" ...	"	Cluster, short, well filled, sweet, and of good flavour.	"
Transparent (white.)	" 26	" ...	"	Cluster, medium in length, open, of good flavour.	"
La Fertile (red).	" 26	" ...	Above medium	Cluster, medium in length, and full, of good flavour.	"
White Gondoin.	" 26	" ...	Medium	Cluster, medium in length, rather open, of good flavour.	Very productive.
La Hative......	" 26	" ...	"	Cluster, medium in length, and fairly full, of good quality.	Productive.
Knight's Early.	" 26	" ...	Small....	Cluster, short, not very full, of good flavour.	Moderately productive.
Prince Albert..	" 26	Moderately vigorous.	Medium......	Cluster long, moderately full, of good flavour.	"
Esperen's White	" 27	Vigorous ...	Large	Cluster, medium in length, and full, sweet and of good flavour.	Fairly productive.

RED AND WHITE CURRANTS—*Concluded.*

Name.	Date of Ripening.	Growth of Plant.	Size of Fruit.	Quality.	Productiveness.
Large White...	June 27	Vigorous....	Large........	Cluster, long and well filled, yellowish white, sweet and of good flavour.	Productive.
White Cherry..	" 27	" ...	Small....	Cluster, medium in length, fairly well filled, mild, sweet, and of good flavour.	Moderately productive.
Red Cherry....	" 27	" ...	Large....	Cluster, long and fairly well filled, of good flavour.	Productive.
White Pearl....	" 27	" ...	Medium......	Cluster, medium, fairly full, of good flavour.	Fairly productive.
Red Dutch.....	" 27	" ...	"	Cluster, medium, fairly well filled, of good flavour.	Productive.

Ada...........	" 10	" ...	Medium	Not very good	Productive.
Gregg	" 12	" ...	Large....	Firm and of good quality.....	"
Progress	" 12	" ...	"	Firm, sweet and of good quality	Fairly productive.
Jackson's May King.	" 12	" ...	Small	Of poor quality	Moderately productive.
Minnie	" 12	" ...	Medium	Dark purple, crumbly, acid, with many imperfect berries	" "
Hopkins......	" 12	" ...	"	Firm and juicy, good	" "

Black cap raspberries require considerable moisture at time of ripening—as well as heat and sunshine—to bring them to the best condition. This year the weather was hot and dry when they were ripening which caused the fruit to dry up, and made them seedy and comparatively tasteless. On this account the quality of the fruit was not as good as usual and the yield was small.

BLACKBERRIES.

A quart each of the following varieties were shipped by express at three different times, to the McPherson Fruit Co., Winnipeg, to test their shipping qualities.

They rank in the following order:—

Eldorado. The best in quality and a good shipper.
Wilson's Early. Equal to the Eldorado as a shipper.
Early Cluster.
Agawam.
Snyder.
Stone's Hardy.
Minnewaska.
Ohmer.
Early King.
Lawton.
Taylor's Prolific.
Kittatinny.

All but the three last varieties reached Winnipeg in fairly good condition. With proper care in picking and crating and a refrigerated car in which to ship, a good many varieties of blackberries could be marketed in Winnipeg from the Pacific coast with profit.

BLACKBERRIES.

Name.	Date of Ripening.	Growth of Plant.	Size of Fruit.	Quality.	Productiveness.
Tecumseh	July 25	Moderately vigorous.	Small	Uneven in shape, inferior in flavour.	Not productive.
Thompson's Mammoth.	" 27	Vigorous	Small to medium.	Berries imperfect and of poor quality.	"
Kittatinny	" 27	"	Large	Fruit rather acid, of fair flavour.	Productive.
Ohmer	" 27	"	"	Fruit moderately firm and of fair flavour.	"
Wilson's jr	" 29	"	Small	Uneven in shape and in ripening, acid, of fair quality.	Not productive.
Lovett's Best	" 30	"	"	Uneven in size and inferior in every way.	"
Oregon Ever-bearing.	Aug. 10 to Sept. 20.	"	Above medium	Acid, but of fair flavour	Productive.
Maxwell	Aug. 10	Moderately vigorous.	Small	Not a very good berry	Not productive.
Child's Tree	" 16	"	"	A poor berry	"
Early King	July 10	Vigorous	Medium	Glossy black, of good flavour	Productive.

APPENDIX

TO THE

REPORT OF THE MINISTER OF AGRICULTURE

ON

EXPERIMENTAL FARMS.

Ottawa, December 1, 1899.

Sir,—I take pleasure in submitting for your approval the thirteenth annual report of the work done, and in progress, at the several Experimental Farms.

In addition to my own report, you will find appended, reports from the following officers of the Central Experimental Farm: From the Agriculturist, Mr. J. H. Grisdale; from the Horticulturist, Mr. W. T. Macoun; from the Chemist, Mr. Frank T. Shutt, and from the Entomologist and Botanist, Dr. James Fletcher. A report is also submitted from the Poultry Manager, Mr. A. G. Gilbert.

From the Branch Experimental Farms there are reports from Mr R. Robertson, Superintendent, and from Mr. W. S. Blair, Horticulturist of the Experimental Farm for the Maritime Provinces, at Nappan, Nova Scotia; from Mr. S. A. Bedford, Superintendent of the Experimental Farm for Manitoba, at Brandon; from Mr. Angus Mackay, Superintendent of the Experimental Farm for the North-west Territories, at Indian Head, and from Mr. Thos. A. Sharpe, Superintendent of the Experimental Farm for British Columbia, at Agassiz.

In these reports there will be found the results of many important and carefully conducted experiments in agriculture, horticulture and arboriculture, the outcome of practical work in the fields, barns, dairy and poultry buildings, orchards and plantations at the several experimental farms; also of scientific investigations in the chemical laboratory and the information gained from the careful study of the life histories and habits of injurious insects and the methods by which noxious weeds are propagated and spread, together with the most practical and economical measures for their destruction. In the report of the Entomologist and Botanist will also be found particulars of the experiments and observations which have been made during the past year in connection with the Apiary.

The large and constantly increasing demand made by the farmers throughout this country for the annual reports and other publications issued from the experimental farms, is a gratifying evidence of the desire for information among this class of the community, also of the high esteem in which these records of the work of the farms are held. It is hoped that the facts brought together in the present issue will be found of much practical value to the Canadian farmer and fruit grower and that they may assist in advancing the interests of agriculture and horticulture in Canada.

I have the honour to be, sir,

Your obedient servant,

WM. SAUNDERS,

Director Experimental Farms.

To the Honourable

The Minister of Agriculture,

Ottawa.

ANNUAL REPORT

OF THE

EXPERIMENTAL FARMS

REPORT OF THE DIRECTOR, WM. SAUNDERS, LL D., F.R.S.C., F.L.S.

The particulars herewith submitted of the operations conducted at the five Dominion Experimental Farms during 1899 for the advancement of agriculture, horticulture and arboriculture will, it is hoped, include much which will be of interest and of value to Canadian farmers. During the thirteen years which have passed since these farms were established great changes for the better have taken place in farm life. The position of the farmer in the community has been improved and his work is now carried on with greater intelligence and with more financial success. In most instances the home has been made more attractive, the family surrounded with greater comforts and much of the drudgery formerly associated with the farmers' calling, has been lifted from his shoulders, by the introduction of methods of co-operation, by improvements in machinery and by the dissemination of valuable experience gained in reference to all branches of farm work in this country. He has thus received benefit from the work of others, has acquired a wider knowledge of the principles which underlie successful farming, and has thus been able to bring more skill to bear on the many sided work in which he has been engaged. The farmer now seldom sells coarse grains from his farm but converts these by feeding, into concentrated animal products and thus retains the elements of fertility which these crops have taken from the land and restores them to the soil in the manure. He thus supplies for future crops much plant food in a readily available form. The experience gained on the Experimental Farms widely disseminated in reports and bulletins has exercised an important influence in bringing about the changes and improvements referred to. In the planning and carrying out of the many experiments explained in the Annual Reports the special needs of farmers residing in the climates in which these farms are located have been carefully considered, and much efficient help has thus been rendered.

CROP RESULTS OF THE PAST SEASON.

The season of 1899 has been characterized by good crops over the greater part of the Dominion, and reference to the particulars of the crops harvested at the several experimental farms will show that the results obtained at these institutions are considerably above the average of the country. The success achieved has been due mainly to a more thorough preparation of the soil, greater care in the preserving and using of barnyard manure, the careful selection of well matured and plump seed of the most productive sorts and early sowing, all of which may easily be put in practice by the average farmer.

The results had in 1899 from the uniform trial plots of grain, fodder corn, roots and potatoes were published as heretofore early in the season in bulletin form, so that the particulars which might influence farmers in the choice of seed were in their hands for consideration in good season. The average results of a five years trial of all the more important sorts furnishes additional evidence in support of the view, that under uniform conditions some varieties are much more productive than others, and that this desirable tendency in some instances is so strong that it asserts itself under all the different climatic and soil conditions which obtain at the Central and Branch Experimental Farms. The relative earliness in ripening which under some conditions is almost as important as productiveness has been further investigated and the results reached confirm the views held by most careful students of this subject that as a rule any great increase in earliness in ripening of grain is accompanied by a decrease in yield.

EARLY, MEDIUM AND LATE SOWINGS.

The experiments which have now been continued for ten years to gain information as to the best time to sow, have furnished evidence so conclusive in favour of early sowing that it will probably not be thought necessary to continue these any longer.

VACANCY IN THE STAFF FILLED.

Early in the year the position of Agriculturist of the Central Experimental Farm which has remained vacant since the resignation of Prof. J. W. Robertson in 1896, was filled by the appointment of Mr. J. H. Grisdale. Mr. Grisdale takes charge of the stock, the dairy and the field crops. The experimental plots will remain under the charge of the Director.

NEW BUILDINGS.

An excellent new root house has been built during the year with substantial stone walls and a superstructure of wood two storeys high. The lower one has been arranged for the storage of the farm wagons, sleighs, &c., with a large room at one end for the distribution of samples of seed grain. The upper storey has been fitted for the storage of miscellaneous material and furnishes also a convenient place for preparing grain and other farm products for exhibition purposes. The size of this building, outside meaurement is 104 ft. by 34.

Two circular silos have also been built to take the place of the two square silos formerly used, which had become so much decayed as to be unfit for further service. The new silos are 16 ft. 10 in. by 30 feet and have capacity for the storage of about 125 tons of ensilage in each.

A suitable building has also been erected for the curing of tobacco, furnishing space sufficient for two or three acres of crop.

EXPERIMENTAL WORK

CONDUCTED AT THE CENTRAL EXPERIMENTAL FARM, OTTAWA, ONTARIO.

EXPERIMENTS WITH OATS.

The number of varieties of oats tested in the uniform trial plots during the season of 1899 was seventy-eight. These experiments have been conducted to gain information as to the relative yield, earliness and other characteristics of the several sorts. The soil was a heavy sandy loam mixed with clay, of good quality which received a dressing of barn-yard manure about 18 tons per acre in the spring of 1893. No fertilizer of any sort has been applied since. The previous crop was wheat. The land was gang-ploughed shallow in 1898 soon after harvest to start weed seeds and shed grain and ploughed again late in autumn about 8 inches deep. In the spring of 1899 it was disc-harrowed twice and harrowed twice with the smoothing harrow before sowing. The seed of all the varieties was sown on May 2, on plots of one-fortieth acre each, two bushels of seed were used per acre and the land was rolled after sowing, just before the grain came up. Among the varieties tested this year were the following 14 cross-bred sorts all of which have been produced on the Experimental Farms. Lawson, Olive, Oxford, Cromwell, Miller, Kendal, Medal, Milford, Russell, Master, Brandon, Holland, King and Pense.

EXPERIMENTS WITH BARLEY.

Fifty-six varieties of barley have been under trial in the uniform test plots during the past season. Twenty-four of these were two-rowed sorts and thirty-two were six-rowed. The land chosen for the barley plots was adjoining that used for the trial plots of oats. The soil was similar and the preparation and treatment of the land the same. The previous crop was wheat. The two-rowed varieties were all sown on May 1 at the rate of 2 bushels of seed per acre and the six-rowed sorts on May 2, using $1\frac{3}{4}$ bushels of seed per acre. The size of the plots was $\frac{1}{40}$th acre each. Among the varieties tested this year are included the following two-rowed and six-rowed sorts, all of which are hybrids which have been produced at the Experimental Farms. Two-rowed sorts, 17, as follows: Sidney, Beaver, Kirby, Fulton, Leslie, Monck, Nepean, Logan, Dunham, Clifford, Victor, Jarvis, Pacer, Gordon, Bolton, Rigid and Harvey. Six-rowed sorts, 17, namely, Claude, Pioneer, Royal, Nugent, Trooper, Summit, Yale, Vanguard, Stella, Argyle, Mansfield, Garfield, Brome, Phœnix, Empire, Albert and Surprise.

EXPERIMENTS WITH FALL WHEAT.

The number of varieties of fall wheat under trial during the past season was twenty-five. These were all sown in plots of one-fortieth of an acre each on sandy loam soil on September 9, 1898. The winter was very unfavourable for this crop. The ground was bare of snow during portions of the early winter months when the temperature was low. In the spring of 1899 all the plots were found to be so badly winter-killed that they were ploughed under.

EXPERIMENTS WITH SPRING WHEAT.

The number of varieties of spring wheat under trial during the past season was sixty-five. The land used for these tests was also adjoining the oat plots but the soil was somewhat heavier and contained a larger proportion of clay. The preparation and treatment of the land was the same. The previous crop was oats. The size of the plots was one-fortieth of an acre each and all were sown on April 28 and 29, at the rate of $1\frac{1}{2}$ bushels of seed per acre. The land was rolled before the grain came up. The varieties tested this year included the following 41 cross-bred sorts, all of which were originated on the experimental farms : Preston, Laurel, Vernon, Captor, Stanley, Percy, Allen, Rideau, Admiral, Beauty, Progress, Weldon, Crown, Harold, Essex, Huron, Dawson, Blenheim, Cartier, Alpha, Chester, Clyde, Benton, Hastings, Bishop, Countess, Cassel, Fraser, Ebert, Crawford, Angus, Advance, Dufferin, Blair, Mason, Plumper, Early Riga, Dawn, Campbell, Byron and Norval.

EXPERIMENTS WITH PEASE.

Sixty varieties of pease were sown on the trial grounds last year on plots of one-fortieth of an acre each. Many of them made good growth and promised fair crops. When most of the plots had been cut and were nearly ready to house, a sudden and violent wind storm arose on the 21st of August, which in a few moments carried the product of a large proportion of the plots to the lower end of the field where they were so mixed that it was impossible to separate them. Under these circumstances no comparisons can be made this year of the yields of the many varieties under trial.

RESULTS OF EARLY, MEDIUM AND LATE SOWINGS.

The tests here recorded which comprise six successive sowings of one week apart were all conducted on similar land on $\frac{1}{20}$th acre plots, the plots adjoining each other. The soil was a sandy loam of fair quality which received a dressing of barn-yard manure, about 12 tons per acre in the autumn of 1895 when it was ploughed under. The land also received an application of unleached wood ashes in November, 1897, of about 125 bushels to the acre. No fertilizers have been applied since. The previous crop was grain in experimental plots, the different kinds of grain being sown in rotation. The land was ploughed very shallow shortly after harvest to start weed seeds, and again later in the autumn about 8 inches deep. In the spring a sufficient quantity of the land for the first set of plots was thoroughly stirred with a two-horse cultivator which loosened the soil about 6 inches deep, and harrowed twice with the smoothing harrow before sowing. The first sowing was made as soon as the land was in fit condition to receive the seed. The oats were sown at the rate of 2 bushels per acre, the Canadian Thorpe barley 2 bushels, the Odessa $1\frac{3}{4}$, the spring wheat $1\frac{1}{2}$ bushels, the Mummy pease $2\frac{1}{2}$ bushels, and the Golden Vine 2 bushels per acre. A sufficient portion of the land for the subsequent sowings was worked up from week to week as it was needed, in the same manner as that for the first set of plots, and in this way any weeds which had started were killed, and each series of plots were given at the outset, the same chance as far as condition of soil was concerned.

SUMMARY OF RESULTS OF EARLY, MEDIUM AND LATE SOWINGS FOR THE WHOLE PERIOD.

The following are the average crops which have been obtained during the full period these tests have been continued, that is ten years with the oats, barley and spring wheat, and five years with pease :—

Tests Continued for Ten Years.									Tests Continued for Five Years.		
Oats.	Average Yield per Acre.		Barley.	Average Yield per Acre.		Spring Wheat.	Average Yield per Acre.		Pease.	Average Yield per Acre.

* The first sowing of spring wheat in these plots in 1899 was so badly injured by standing water during the extremely wet weather in July that the returns in this connection would be misleading. The figures given in this instance cover only 9 years test.

SUMMARY.

The results of this ten years' trial of early, medium and late sowings of oats, barley and spring wheat should be carefully noted by every farmer in Ontario and Quebec. The experiments have been conducted on a piece of land very uniform in character with the same preparation and treatment and the same seed has been used in each case. There seems no reason to doubt that the results which have been had have been almost wholly due to the period of seeding. They show that the period when the second sowing in these experiments has been made, that is about one week after the ground is in that condition that sowing is practicable, is the most favourable time for the sowing of these crops at Ottawa.

LOSS IN CROP OF OATS BY DELAY IN SOWING.

These experiments show that in the sowing of oats a delay of one week beyond the time spoken of has caused an average loss of over 15 per cent, two weeks a loss of 22 per cent, three weeks a loss of over 32 per cent, and a delay of four weeks has resulted in an average loss of about 48 per cent of the crop.

LOSS IN CROP OF BARLEY BY DELAY IN SOWING.

With barley a delay of one week in sowing beyond the most favourable period shows an average loss of 23 per cent, a delay of two weeks a loss of more than 27 per cent, three weeks about 40 per cent and a delay of four weeks has entailed an average loss of nearly 46 per cent.

LOSS IN CROP OF SPRING WHEAT BY DELAY IN SOWING.

In the case of spring wheat a delay of one week beyond the period which these experiments show to have been most favourable has entailed a loss of over 30 per cent, two weeks fully 40 per cent, three weeks nearly 50 per cent, and a delay in sowing of four weeks beyond the time referred to has involved an average loss of over 56 per cent.

LOSS IN CROP OF PEASE BY DELAY IN SOWING.

The results obtained from the five years' trial of early, medium and late sowings of pease show that about a week after the ground is in that condition to make seeding practicable is the most favourable for this crop. That a delay of one week beyond this

period has caused an average loss of about 4 per cent, a delay of two weeks about 12 per cent, three weeks about 22 per cent, and a delay of four weeks has lessened the crop on an average over 30 per cent.

These experiments have now been continued long enough to demonstrate most conclusively how important it is that farmers should sow all their grain crops promptly and if possible within ten days after the ground,—prepared by ploughing in the autumn,—is ready for seeding. If this practice were to become universal the average crop in these provinces would be very much increased.

EXPERIMENTS WITH INDIAN CORN.

Thirty-three varieties of Indian corn were tested during the season of 1899 side by side on fairly uniform land. The soil was a sandy loam of medium quality which received a dressing of barn-yard manure, about twelve tons to the acre during the winter of 1898-9. This was placed on the frozen land fresh from the barn-yard in small heaps of about one-third of a cart load each and spread and ploughed under in the spring. The previous crop was spring wheat. The land was gang-ploughed shallow shortly after harvest to start weed seeds and shed grain, and ploughed again in the autumn 7 or 8 inches deep. In the spring of 1899, after the manure was ploughed under, it was twice harrowed with the smoothing harrow before sowing. The corn was sown with the seed drill in rows 3 feet apart, and subsequently the plants were thinned so as to leave them from 6 to 8 inches apart in the rows.

The varieties were all sown on May 25, and were cut for ensilage on September 14. The yield per acre has been calculated from the weight of the crop cut from two rows, each 66 feet long.

INDIAN CORN SOWN AT DIFFERENT DISTANCES.

Three varieties of Indian corn were chosen for this test, the Longfellow, Selected Leaming and Champion White Pearl. These were sown in rows at four different distances, namely, 21, 28, 35 and 42 inches apart. The object of the experiment was to gain information as to the weight of crop produced when sown under these different conditions. The soil was a sandy loam of fair quality and the previous crop was wheat. The land was ploughed in 1898, soon after harvest, very shallow to start weed seeds and shed grain, and ploughed again later in the autumn about 7 inches deep. During the winter of 1898-9 barn-yard manure was applied to this land in the proportion of about 12 tons per acre. The manure was taken fresh from the barn-yard, and distributed over the land in small piles of about one-third of a cart load each to avoid fermentation. In the spring of 1899 the manure was spread and ploughed under about 6 inches deep and harrowed twice with the smoothing harrow before sowing. The corn was sown with the seed drill on May 25, and was cut for ensilage on September 14. Four rows were planted in each case, and the yield per acre has been estimated from the weight obtained from the two inside rows, each 66 feet long.

Particulars of the results are given in the following table:—

Name of Variety.	Width of Row.	Character of Growth.	Height when Cut.	Condition when Cut.	Weight per Acre.	
	Inches.		Feet.		Tons.	Lbs.

EXPERIMENTS WITH TURNIPS.

Twenty-five varieties of field turnips were tested during the past season, all sown side by side on similar land. The soil was a sandy loam of medium quality, which was manured during the winter of 1898–9, with about 12 tons of barn-yard manure per acre. The manure was taken fresh from the barn-yard during the winter, and put on the frozen land in small piles of about one-third of a cart load each and spread in the spring, when it was ploughed under about 6 or 7 inches deep and harrowed twice with a smoothing harrow. The land was then made up in drills 2 feet apart, and subsequently rolled with a heavy land roller, which flattened the drills nearly one half, leaving a firm seed bed. The seed was sown at the rate of 3 pounds per acre. Three sowings were made of each variety, the first on May 12, second on May 26, and the third on June 8, and all were pulled on October 14. The yield per acre has been calculated from the weight of roots pulled from one row 66 feet in length.

These turnips were sown in single rows across a field of 400 feet or more in length which gave opportunity for further experiment after the row of 66 feet, used to ascertain the yield on October 14, had been pulled. A portion of these roots were left in the

ground until later, to gain information as to what advantage, if any, arises from leaving turnips in the ground after the middle of October. All the varieties under test were so left until November 3, which allowed twenty-one days for additional growth. The results were as follows :—

TURNIPS.—TEST OF VARIETIES.—YIELD FROM FIRST PULLING, OCTOBER 14.

	Average yield of the several sowings when pulled late (Nov. 3)	32	4	27	383	24	812

By comparing the average crops here given with those given in the preceding table it will be seen that the turnips gained in weight during the twenty-one days additional time given them as follows :

	Tons.	Lbs.
1st Sowing average gain per acre	1	1,907
2nd " " "	1	1,250
3rd " " "	1	844

An average gain on the three sowings of all the varieties tested of 1 ton 1,333 pounds per acre.

EXPERIMENTS WITH MANGELS.

During the year 1899, twenty-one varieties of mangels were under test. These were all sown side by side adjoining the turnips. The land was similar and the treatment and preparation was the same. The previous crop was barley. The drills were made up 2 feet apart and rolled with a heavy land roller to make a firm bed before the seed was sown. Two sowings were made, the first on May 11, and the second on May 25. The roots were all pulled on October 13, and the yield per acre has been calculated from the weight of roots gathered from one row 66 feet long.

The average crop of the first sowing exceeded that from the second sowing by 10 tons, 1,206 pounds per acre.

EXPERIMENTS WITH CARROTS.

Twenty varieties of carrots were under trial during 1899, all sown side by side adjoining the turnips and mangels. The land was similar and the treatment and preparation was the same. The previous crop was pease. Drills were made up 2 feet apart and rolled with a heavy land roller to make a firm bed before the seed was sown. Two sowings were made, the first on May 11, and the second on May 25. The roots were all pulled on October 13, and the yield per acre has been calculated from the weight of roots gathered from one row 66 feet long.

The average crop of the first sowing exceeded that from the second sowing by 2 tons 1,791 pounds per acre.

EXPERIMENTS WITH SUGAR BEETS.

Six varieties of sugar beets were tested in 1899. These were sown side by side on land adjoining that used for the trial plots of turnips, mangels and carrots. The soil was similar and the treatment preparation and method of sowing was the same. The previous crop was pease. Two sowings were made, the first on May 11, the second on May 25. The roots were all pulled on October 13, and the yield per acre has been calculated from the weight of roots gathered from one row 66 feet long.

The average crop of the first sowing exceeded that of the second sowing by 5 tons 1,852 pounds per acre.

(POTATOES.)

The records of the results of the experiments with potatoes will be found in the report of the Horticulturist.

EXPERIMENTS WITH CLOVER.

Additional information has been gathered during the past year as to the benefit resulting to land from the ploughing under of green clover. The experience gained with crops grown on land so treated has shown that there is an increase in vigour of growth as well as a material addition to the weight of crop produced.

RESULTS OF SOWINGS OF OATS AFTER CLOVER.

Early in the spring of 1899 a field of four acres of land was ploughed about 4 inches deep. The soil was a sandy loam of medium quality, on two acres of this land barley had been grown in the spring of 1898 and with it 10 pounds of red clover seed had been sown. After the grain was harvested the clover made a rapid growth and before winter set in it had formed a good mat of foliage about a foot high. One acre had been in Brome grass, *Bromus inermis*, in 1898 ; half an acre had been sown with a mixture of pasture grasses without clover and another half acre with a mixture of pasture grasses associated with a good proportion of clover.

After ploughing and harrowing, the whole area of four acres was sown with one variety of oats—the Bavarian. Where clover had been ploughed under its effect was very clearly shown on the growth of the oats, the crop grown after clover was much greener in colour and more vigorous in growth of both leaf and stalk and when measured about the time the heads of grain were shooting out, the plants on an average were about a foot taller than the oats on the adjoining land where no clover had been used.

When harvested the results were as follows :—

	Per acre Bush.	Lbs.
1 acre of oats sown after Brome grass gave	33	8
½ acre after mixture of pasture grasses without clover......	36	16
½ acre after mixture of pasture grasses with clover........	46	4
2 acres sown after barley with clover....................	43	28

The average of the crop sown where no clover had been used was 34 bushels 10 pounds per acre, the average of that sown after clover was 44 bushels 10 pounds, a difference of ten bushels per acre in favour of the crops grown after the ploughing under of clover.

EFFECT OF CLOVER ON CROPS THE SECOND YEAR AFTER PLOUGHING UNDER.

In the Annual Report of the Experimental Farms for 1898, page 45, the results were given of the crops of Banner oats grown on eight plots of one-twentieth of an acre each which had been sown with grain in 1897 ; on four of these the grain had been grown that year with clover and on the other four plots the grain had been grown without clover. The results had in 1898 shewn a considerable increase in the weight of straw harvested and an average increase in yield of grain on the plots where clover had been used of a little over 11 bushels per acre.

In 1899 these plots were all sown with one variety of barley, the Mensuary, and again we find marked differences in favour of the land treated with clover. No other fertilizer has been used.

INCREASE IN YIELD OF STRAW BY THE PLOUGHING UNDER OF GREEN CLOVER.

These figures show that the average yield of straw from the four plots treated with clover was for the first year 3,560 pounds per acre and for the second year 2,870 pounds, whereas the weight of straw obtained from the adjoining plots where no clover was used was 1,990 pounds per acre in 1898, and 2,125 pounds per acre in 1899. This shows a larger yield of straw where clover was used of 1,570 pounds per acre the first year and 745 pounds the second year.

INCREASE IN YIELD OF GRAIN BY THE PLOUGHING UNDER OF GREEN CLOVER.

The average increase in grain after the ploughing under of green clover was for the first year when oats were used, 11 bushels 1 pound per acre, and in 1899, when these same plots were sown with barley the average increase was 8 bushels 31 pounds per acre.

These results are indeed remarkable. They show that in the case of the plots under consideration that the ploughing under of a single crop of clover, sown with the grain in 1897, produced a wonderful increase both in straw and grain. From the added fertility and humus thus supplied the crop of straw, when compared with the adjoining plots on which no clover was used, was increased 78 per cent in 1898 and 35 per cent in 1899. The increase in the crop of grain was still more remarkable, since it shows a slightly higher percentage for the second year than it did for the first. The increase in the weight of grain on the plots treated with clover were in 1898 over 28 per cent whereas in 1899, they were over 29 per cent,

INCREASE IN YIELD OF POTATOES BY THE PLOUGHING UNDER OF GREEN CLOVER.

In the spring of 1899 a piece of rather light sandy loam of fair quality, was planted with potatoes of the variety known as Daisy. Nine rows of these were planted 560 feet long and 2½ feet apart on land on which barley had been grown the previous year. Common red clover had been sown with the barley in the propertion of 10 pounds of seed per acre. After the grain was cut, the clover made a rapid growth and had formed a good mat of foliage about 12 inches high by the middle of October, when it was

ploughed under about 7 or 8 inches deep. On land adjoining of the same quality and which had received similar cultivation, nine rows of the same variety of potatoes were planted on the same day. The previous crop on this latter piece of land had been on about ¾th of it pease and the other ¼th carrots.

The potatoes were planted on May 25, came up June 12, and were dug October 3,

On plot 1—Following barley, with clover turned under in October, 1898, the potatoes gave a total yield of 4,208 pounds.

On plot 2—Following pease and carrots, where no clover had been sown, the total yield was 3,025 pounds.

These results show a difference in favour of the crop where clover was used of about 28 per cent. The foliage of the potatoes grown after clover was much more vigorous and even, and was of a deeper green colour.

EXPERIMENTS WITH SOJA BEANS.

(Soja hispida.)

Experiments have been conducted in the growing of an early ripening variety of Soja beans for fodder purposes for the past three years, with the object of finding out the best time to plant and the most successful method of planting. Four plots of one-fortieth acre each were used for this purpose. The soil was a sandy loam of medium quality but somewhat variable. The previous crop was pease. The land was gang-ploughed soon after harvest and ploughed again later in the autumn about 7 inches deep. In the spring of 1899 it received a dressing of barn-yard manure, about 12 tons per acre. This was spread and ploughed under about 6 inches deep and harrowed twice with the smoothing harrow before sowing.

The beans were sown with the seed drill in rows 14, 21, 28 and 35 inches apart and cultivated twice during the season with a horse cultivator. They were all sown on May 31, and were cut for ensilage on September 15.

Plot 1. Sown in rows 14 inches apart. Growth strong and even, very leafy, average height 38 to 40 inches. The pods were just forming at the time the crop was cut. Yield of green fodder, 12 tons 800 pounds per acre.

Plot 2. Sown in rows 21 inches apart. Growth strong and even, very leafy, average height 40 to 44 inches. The pods were well formed, but the beans were still soft when the crop was cut. Yield of green fodder, 12 tons 1,600 pounds per acre.

Plot 3. Sown in rows 28 inches apart. The growth on this plot was medium but even; the weaker growth and smaller yield of this plot and the next was partly due to the soil being lighter. The plants were fairly leafy, and their height was from 40 to 44 inches. The pods were well formed at the time of cutting, and the beans of full size and beginning to harden. Yield of green fodder, 5 tons 1,600 pounds per acre.

Plot 4. Sown in rows 35 inches apart. Growth medium and even, fairly leafy; height, 40 to 44 inches. The plants were well podded, pods more numerous than on those plants in plot 3. The beans were beginning to harden at the time of cutting. Yield of green fodder, 4 tons 1,200 pounds per acre.

EXPERIMENTS WITH HORSE BEANS.

(Faba vulgaris var equina).

Four plots of one-fortieth acre each were devoted to experiments with this crop. The land was adjoining that used for the Soja beans. It was similar in character and quality, and received the same treatment and preparation. The previous crop was

pease. Imported seed was used, of the variety known as Tick beans. The object of this experiment was to gain information as to the crops obtainable from sowings made in rows at different distances apart. The beans were sown with the seed drill in rows 14, 21, 28 and 35 inches apart. All the plots were sown on May 17, and the crop was cut for ensilage on September 15. There was no blight on the plants this year.

Plot 1. Sown in rows 14 inches apart. The growth was medium to strong and even; height, 50 to 55 inches; length of pod, 2 to 2½ inches; plants well podded and beans nearly ripe at time of cutting, yield, 10 tons 1,880 pounds per acre.

Plot 2. Sown in rows 21 inches apart. Growth strong and even; height, 50 to 55 inches. Plants all well podded. Length of pods, 2 to 2½ inches; yield, 12 tons 1,640 pounds per acre.

Plot 3. Sown in rows 28 inches apart. Growth strong and even; height, 50 to 55 inches. Most of the beans on the plants on this plot were ripe at the time of cutting. Yield per acre, 5 tons 600 pounds.

Plot 4. Sown in rows 35 inches apart. Growth medium but even; height, 46 to 51 inches. The crop on this plot was well ripened, and the plants had lost much in weight by drying before it was cut. Yield per acre, 3 tons 1,200 pounds.

EXPERIMENTS WITH MILLETS.

Seven varieties were sown on plots of one-fortieth acre each; all were sown in drills 7 inches apart except the Japanese millet, which was sown in rows 9 inches apart. The soil was a sandy loam of medium quality; the previous crop was pease. The land received a dressing of barn-yard manure in the fall of 1898, which was spread out of the wagon and ploughed under to the the depth of 6 or 7 inches. In the spring of 1899, the ground was harrowed twice with the disc harrow and twice with the smoothing harrow before sowing. The seed was sown with a Planet Junior seed drill and all were sown on May 27.

	Name of Variety.	Date Cut.	Length of Straw in inches.	Character of Growth.	Weight, per acre, green.		Weight, per acre, dry.	
					Tons.	Lbs.	Tons.	Lbs.

These were all cut when the seed was in the soft or doughy stage.

SPECIAL EXPERIMENTS WITH FERTILIZERS.

In the annual report of the Experimental Farms for 1893, details were given on pages 8 to 24 of the results of a series of tests which were carried on during the previous five or six years with the object of gaining information regarding the effects which follow the application of certain fertilizers and combinations of fertilizers on the more important farm crops. The particulars there given covered the results of six years' experience with crops of wheat and Indian corn, and five years' experience with crops of oats, barley, turnips and mangels. The results of similar tests conducted for three years with carrots and one year with sugar beets were also given.

These experiments have been continued; and as explanatory regarding the preparations made and the general plan, together with the way in which they have been carried on, the following paragraphs are quoted from the report of 1893 :—

'A piece of sandy loam, more or less mixed with clay, which was originally covered with heavy timber, chiefly white pine, was chosen for these tests. The timber was cut many years ago, and among the stumps still remaining when the land was purchased, there had sprung up a thick second growth of trees, chiefly poplar, birch and maple, few of which exceeded 6 inches in diameter at the base. Early in 1887, this land was cleared by rooting up the young trees and stumps and burning them in piles, on the ground from which they were taken, the ashes being afterwards distributed over the soil as evenly as possible, and the land ploughed and thoroughly harrowed. Later in the season it was again ploughed and harrowed, and most of it got into fair condition for cropping.

'The plots laid out for the experimental work with fertilizers were one-tenth of an acre each, 21 of which were devoted to experiments with wheat, 21 to barley, 21 to oats, 21 to Indian corn or maize, and 21 to experiments with turnips and mangels. It was not practicable to undertake work on all the plots the first season. The tests were begun in 1888 with 20 plots of wheat and 16 of Indian corn, and in 1889 all the series were completed excepting six plots of roots, Nos. 16 to 21 inclusive, which were available for the work in 1890.' In all cases the plots in each series have been sown on the same day.

'In 1890 it was found that all the grain plots had become so weedy that the growth of the crops was much interfered with, and with the view of cleaning the land one-half of each of the wheat and oat plots was sown with carrots in 1891, and one-half of each of the barley plots with sugar beets. In 1892 the other half of each plot in each of these series was sown with carrots. In 1893 it was thought desirable to continue this cleaning process, and carrots were again sown on the half of the wheat and oat plots occupied with this crop in 1891, and also on the half of the barley plots cropped with sugar beets that year." In 1894, 1895, 1896, 1897 and 1898 the one-half of the oat plots were sown again with carrots and the half of the plots devoted to wheat and barley were planted with potatoes.

TREATMENT OF SOIL.

"The treatment of the soil on all the grain plots has been to gang-plough soon after harvest, and after the shed grain and weeds have well started to plough again later, about 7 inches deep. In spring the plots have been gang-ploughed once before applying the fertilizers, which are then scattered over the surface and harrowed with the smoothing harrow before sowing. On those plots where barn-yard manure has been used, the manure has been lightly ploughed under as soon as possible after it has been spread on the land and just before sowing. Wherever barn-yard manure is spoken of, it is understood to be a mixture of horse and cow manure in about equal proportions.'

A summary of these permanent fertilizer plots is given each year, taking the average yield of the whole previous period, adding the results of the current year, and then giving the average yield for the full time.

CHANGES MADE IN THE EXPERIMENTS.

After ten or eleven years of constant cropping it was found that the soil on those plots to which no barn-yard manure had been applied was much depleted of humus, and hence its power of holding moisture had been lessened and the conditions for plant growth apart from the question of plant food had on this account become less favourable. In 1899 the experiments were modified and an effort made to restore some proportion of the humus and at the same time gain further information as to the value of clover as a collector of plant food. In the spring 10 pounds of red clover seed per acre was sown with the grain on all the plots of wheat, barley and oats, all of which occupied the full one-tenth acre plots. The clover seed germinated well, and after the grain was cut the young clover plants made rapid growth and by October there was a thick mat of foliage varying in height and density on the different plots which was ploughed under October 12.

Ten years' experience had shown that the finely-ground untreated mineral phosphate was of no value as a fertilizer. This substance had been used every year in each series of tests on plots 4, 5, 6, 7 and 8 excepting in the experiments on roots, where it was used on plots 4, 5, 6 and 7. On all these plots the use of the finely-ground untreated mineral phosphate was discontinned in 1898, when there was used in its place similar weights of the Thomas' Phosphate Powder. In 1899 the Thomas' Phosphate Powder was again used on all these plots excepting No. 6 in each series.

Another direction in which information was sought was in reference to the length of time which a liberal application of barn-yard manure would continue to affect subsequent crops, and in 1899 on plots 1, 2 and 6 the barn-yard manure, which had been used for ten or eleven years in succession, was discontinued. The phosphate fertilizer was also omitted on plot 6 in each series. The growing of carrots and potatoes on one-half of the cereal plots was discontinued, and each plot of the wheat, barley and oats occupied the full tenth acre.

WHEAT PLOTS.

The seed sown on each of these plots from the beginning has been in the proportion of $1\frac{1}{2}$ bushels per acre, excepting in 1894; and the varieties used were as follows: In 1888–89–90 and 1891 White Russian, and in 1892–3 Campbell's White Chaff. In 1894 the Rio Grande wheat was used, and shortly before sowing, it was tested as to vitality and found to be deficient in germinating power,—less than half the kernels sprouted. As it was not practicable then to secure better seed, double the usual quantity was sown, namely, 3 bushels per acre, which gave a proportion of growth on each plot of about the usual thickness. In 1895, 1896, 1897, 1898 and 1899, Red Fife wheat was used in the usual quantity of $1\frac{1}{2}$ bushels per acre. In 1899 the Red Fife was sown May 5, came up May 13, and was ripe from August 17 to 20.

The season of 1899 was moderately favourable for the growing of spring wheat at Ottawa and has given in most instances crops above the average.

*Finely ground mineral phosphate was used on this plot from 1888 to 1897. Thomas' phosphate in 1898 only.

BARLEY PLOTS.

The quantity of seed sown per acre on the barley plots was 2 bushels in 1889, 1890 and 1891, $1\frac{1}{2}$ bushels in 1892 and 1893, and 2 bushels in 1894, 1895, 1896, 1897, 1898 and

1899. Two-rowed barley has been used for seed throughout the whole period. The varieties used were as follows: 1889, 1890 and 1891, Saale; 1892, Goldthorpe; 1893, Duck-bill; and in 1894, 1895, 1896, 1897, 1898 and 1899, Canadian Thorpe, a selected form of the Duck-bill. In 1899 the Canadian Thorpe was sown on May 5, came up May 13 and was harvested on August 7 and 8.

In 1899 the yields of eleven of the barley plots were above the average of past seasons, the others were below the average.

*Finely ground mineral phosphate was used on this plot from 1888 to 1897. Thomas' phosphate in 1898 only.

OAT PLOTS.

The quantity of seed sown per acre on the oat plots, was 2 bushels in 1889 and 1890; $1\frac{1}{2}$ bushels in 1891, 1892 and 1893, and 2 bushels in 1894, 1895, 1896, 1897, 1898 and 1899. The varieties used were as follows: In 1889, Early English; in 1890, 1891, 1892, 1893, Prize Cluster; and in 1894, 1895, 1896 1897, 1898 and 1899, Banner. In 1899 the Banner was sown May 8, came up May 14, and the plots were harvested from the 8th to 11th of August. The season of 1899 was favourable for the oat crop, and in most instances the return has been above the average.

INDIAN CORN PLOTS.

The experiments with the plots of Indian corn have been conducted with the object of obtaining the largest weight of well matured green fodder for the silo, and to have the corn so far advanced when cut, that the ears shall be as far as is practicable in the late milk, or glazed condition. Each plot has been divided from the outset into two equal parts, on one of which—known as No. 1—one of the stronger growing and somewhat later ripening sorts has been tried, and on the other, marked No. 2, one of the earlier maturing varieties. During the first four years one of the Dent varieties was tested under No. 1. The Mammoth Southern Sweet was tried in 1888, 1889 and 1890. In 1891 the Red Cob Ensilage was used, and in 1892, 1893, 1894, 1895, 1896, 1897, 1898 and 1899 a free growing Flint variety, the Rural Thoroughbred White Flint, was tested. On the other half of the plot (No. 2) the Canada Yellow Flint was used in 1888, 1889 and 1890, the Thoroughbred White Flint in 1891 Pearce's Prolific in 1892, 1893 and 1894, and the Mammoth Eight Rowed Flint in 1895, 1896, 1897, 1898 and 1899. For the first four years the No. 1 series was planted in drills 3 feet apart, using about 24 pounds of seed to the acre and thinning the plants, when up, to 6 or 8 inches, and the No. 2 in hills 3 feet apart each way and 4 or 5 kernels in a hill. During the past seven years both sorts have been grown in hills. The corn in both series of plots was planted in 1899 on May 25, and cut September 15. In every instance the yield of fodder on these plots during the past season has been below the average of previous years.

PLOTS OF MANGELS AND TURNIPS.

In conducting these experiments the roots only have been taken from the land, the tops have always been cut off and left on the ground to be ploughed under, so that the plant food they have taken from the soil may be returned to it. One-half of each one-tenth acre plot in the series has been devoted to the growth of mangels, and the other half to turnips, and these crops have been alternated from year to year. The preparation of the land has been the same for both these roots. It was ploughed in the autumn after the crop was gathered, gang-ploughed deeply in the spring after the barn-yarn manure had been spread on plots 1, 2 and 6, and after gang-ploughing the other fertilizers were spread by scattering them evenly over the surface, after which it was all harrowed with the smoothing harrow, then made in ridges 2 feet apart, rolled and sown.

In 1889, the variety of mangel used was the Mammoth Long Red. In 1890, three varieties were sown : 15 rows of Mammoth Long Red, 6 of Mammoth Long Yellow, and 6 of Golden Intermediate on each plot. In 1891, each plot again had three varieties : 18 rows of Mammoth Long Red, 3 of Yellow Fleshed Tankard, and 6 of Golden Tankard. In 1892, 1893, 1894, 1895, 1896, 1897, 1898 and 1899, one variety only was used, namely, the Mammoth Long Red. About 4 pounds of seed were sown per acre, each year. In 1899 the mangels were sown May 8, came up May 17, and were pulled October 16.

Two varieties of turnips were sown on the half plots devoted to these roots in 1889; 25 rows of Carter's Prize Winner, and 2 rows of Carter's Queen of Swedes, and in 1890, a single variety, Carter's Elephant Swede. In 1891, six varieties were sown; 6 rows of Lord Derby Swede, 4 of New Giant King, 3 of Imperial Swede, 6 of Champion Swede, 4 of Purple Top Swede, and 4 of East Lothian Swede. In 1892 the Improved Purple Top Swede only was sown, in 1893 and 1894 the Prize Purple Top Swede, in 1895 the Imperial Swede, and in 1896, 1897, 1898 and 1899 the Prize Purple Top Swede. The land used for the turnips, which are usually sown later than the mangels, was prepared in the same manner and the fertilizers spread on it at the same time as for the mangels. It was then allowed to stand until the day before sowing, when it was gang-ploughed shallow or cultivated to kill weeds and loosen the soil, ridged, rolled and sown. In 1899 the turnips were sown June 7, came up June 12, and were pulled October 20. In most instances the yield of both turnips and mangels in 1899 was below the average of past seasons.

Since the grain grown on the fertilized plots during the past year has occupied in each case the full one-tenth acre, there has been no opportunity of continuing the experiments with carrots and potatoes.

NEW HARDY HYBRID FRUITS FOR THE CANADIAN NORTH-WEST.

During the spring of 1897, shortly after the work of the Experimental Farms was begun, a number of varieties of seeds were kindly forwarded to the Director by the late Dr. Regel, who at that time had charge of the Royal Botanic Gardens at St. Petersburgh, Russia. Among these was a package of the seed of *Pyrus baccata* a wild form of crab-apple known as the berried crab, a native of the northern parts of Siberia. Young trees were grown from this seed, and in 1890 and 1891 specimens were sent to the Experimental Farms at Brandon, Manitoba, and at Indian Head in the North-west Territories, to test their hardiness in those localities. These trees have been found quite hardy at both of these western experimental farms, and have started from the terminal buds on the branches every year since they were planted.

As this was the only form of the apple which had proven hardy in the Canadian North-west, after several years experience had established its hardiness, a series of experiments were instituted to improve the size and quality of the fruit, which in its native form is not much larger than a cherry, and is often quite astringent. The trees, however, bear fruit abundantly.

In the spring of 1894 this small wild crab was crossed with several varieties of hardy apples such as Tetofsky and Wealthy, also with some of the larger crabs, including Transcendent, Orange and Hyslop. The seeds obtained from these crosses were sown in the autumn of that year and germinated the following spring, producing in all about 160 thrifty young trees. These were planted the next year in a small orchard, in rows 5 feet apart each way. Some of them have grown very rapidly and have made shapely young trees. During the past season (1899) 36 of these trees have fruited and some of them have borne heavy crops. The fact that so many of these cross-bred trees have fruited on the fourth year from the sowing of the seed is very encouraging and indicates a very early bearing habit. Of the 36 trees which have fruited this year, five have borne fruit of such size and quality as to justify their being named and propagated. Several others among those which have fruited are promising and will be further tested. Most of those of less promise have been dug up and destroyed, so as to give the remaining specimens more room. Following are the names and descriptions of the five varieties referred to, given in what is believed to be the order of their merit.

CHARLES—(Fig. 2, Plate 1.) A cross of Tetofsky male on *Pyrus baccata* female. Tree a very upright and vigorous grower with large leathery leaves. See Fig. 2, Plate 1. The blossoms are deep pink in bud, pinkish white when open, large with wide petals. The fruit set well and the tree was fairly well laden, the fruit being distributed very evenly over the tree. It was ripe September 3, size $1\frac{9}{16}$th inches across, $1\frac{6}{16}$th inches deep, very distinctly ribbed. Colour a uniform yellow, very attractive. Flesh yellow, solid, crisp, juicy, mildly acid with a pleasant flavour, and slightly astringent. The skin is thin and the fruit bakes well. When compared with the Transcendent crab, the size was practically the same, and the acidity and astringency a little less; stem long, calyx persistent.

NOVELTY.—(Fig. 3, Plate 1.) A cross of Wealthy male on *Pyrus baccata* female. Tree fairly upright and a vigorous grower with good foliage On this tree there were only a few bunches of blossoms, which were deep pink in bud, white when open, flowers large, petals broad. Fruit ripe September 19. Size, $1\frac{1}{2}$ inches across and $1\frac{1}{4}$ inches deep, smooth, colour deep red. Flesh a pale yellowish pink, firm, crisp and juicy, sub-acid and of fair quality. Stem long, calyx usually persistent; bakes well. The largest and best of the Wealthy crosses which have yet fruited.

AURORA.—(Fig. 4, Plate 1.) A cross of Tetofsky male on *Pyrus baccata* female. Tree a vigorous grower, upright in habit, leaves large, thick and leathery, blossomed freely. Flowers deep pink in bud, large when open and pure white, petals broad. The fruit set freely and was ripe September 11. Size $1\frac{7}{16}$ inches across, $1\frac{3}{16}$ inches deep. Colour bright red almost all over; very pretty; flesh crisp, juicy, acid and of fair flavour; astringency very slight. When baked this fruit is acid, but of good flavour. Stems long, calyx persistent.

PROGRESS.—(Fig. 1, Plate 1.) A cross of Wealthy male on *Pyrus baccata* female. The tree is a vigorous grower and fairly upright in habit. It blossomed freely; the blossoms were deep pink in bud, pinkish white when open, flowers large, petals wide. Fruit ripe September 14. Size $1\frac{5}{16}$ inches across and $1\frac{3}{16}$ inches deep. Colour red, with some yellow and with a dark red cheek. Flesh very firm, crisp, sub-acid, juicy, astringency scarcely preceptible; of fair flavour. Stem long, calyx persistent. On plate 1, fig. 5, the fruit of *Pyrus baccata* is represented of natural size.

Prairie Gem.—A cross of Tetofsky male on *Pyrus baccata* female. This tree is a moderately vigorous grower, and rather spreading in habit. It was covered with blossoms, which were pink in bud, white when open, of medium size, with petals of medium width, and was covered with fruit from top to bottom. The fruit was ripe August 30. Size 1 inch across and 1 inch deep. Colour brilliant yellow and crimson. Flesh crisp, juicy, acid; flavour good, almost free from astringency; excellent for jelly. Deficient in size but promising for its earliness, quality and profuse bearing habit. On plate 3 a specimen of this fruit is shown of the natural size, also a branch of the same laden with fruit.

All these varieties are remarkable for the persistent manner in which the fruit is attached to the tree. The stems are so firmly fastened that they require a considerable effort to detach them. The trees are all very strongly built with the branches bound to the trees with bands of woody fibre which are difficult to break. Root grafts were made of some of these varieties in the spring of 1898, chosen on account of their promising growth. A number of these were sent at that time to Brandon and Indian Head, and thirty-one specimens of twenty-two varieties survived the winter at Indian Head and had made fair growth by the close of the season in 1899. At Brandon seventy-four specimens of twenty-five varieties passed safely through the winter of 1898 and made fair growth in 1899. In both these collections the variety named Charles is represented, three trees of this apple survived at Brandon and two at Indian Head. A further supply of root grafts of promising sorts was sent last spring, and now that the fruit of the five varieties referred to has proven of value these will be propagated more freely and arrangements are in progress for testing them in many different parts of the North-west country. There is every reason to expect that they will prove generally hardy and that they will be highly appreciated. It is not expected that these new fruits will be much esteemed where larger fruits can be grown, but if they can be grown without special care or protection by farmers generally throughout the North-west country and the colder sections of Ontario and Quebec where the larger sized apples do not succeed, they will prove a great boon to the settlers in those districts, and furnish a wholesome and healthful addition to the food of the people.

Since five good sorts have been found among the first thirty-six of these crosses which have fruited, it is probable that many other equally good or possibly superior sorts will occur among the many cross-bred trees,—about 270 now growing at Ottawa—which have not yet fruited.

Another series of crosses have been made on a species of *Pyrus* known as *Pyrus prunifolia* and its hardiness has been established by a test of several years on both of the North-west experimental farms. The natural fruit of this species is nearly double the size of *P. baccata*. The first crosses in this line were made in 1896, and some of the trees from this source are now two years old and are strong and vigorous in growth. The varieties of the different crosses with *Pyrus prunifolia* number about 200 in all, among which there will no doubt be many interesting sorts.

The results reported are but the first steps in a series of experiments which are full of promise. As the more useful of these hybrids bear fruit the seeds of the finest specimens are being sown from which we may expect many interesting sports. Now that the continuity of nature has been broken by the work of cross-fertilizing, the method of selection will be brought to bear on the best of the seedlings, from some of which increase in size and improvement in quality of fruit may be looked for, and within a few years we shall doubtless have from these sources a considerable number of useful sorts of apples ripening at different periods in the season which will endure the climate of all the settled parts of the North-west country.

DISTRIBUTION OF SEED GRAIN.

In 1899 a further distribution of seed grain was made consisting mainly of sample of the most promising sorts which have been tested at the several experimental farms. These distributions are designed to place within reach of farmers for the improvement

of seed, pure samples and true to name of the best and most productive varieties in cultivation. By the careful handling of one of these samples of 3 pounds of grain, any farmer can soon obtain sufficient seed to sow a large area and may thus in a short time be provided with some of the best sorts, without cost beyond that of his own labour. This part of the farm work is much commended and highly appreciated by a very large number of practical farmers and the need of the work is shown by the large demand each year for samples.

Preparations have been made for another distribution in 1900, which will consist as heretofore of the most promising sorts of oats, barley, spring wheat, pease, Indian corn and potatoes. The several branch farms will also again distribute samples to farmers residing in the provinces and territories where these farms have been established.

The samples sent out from the Central Experimental Farm during the early months of 1899, were distributed as follows.

Kind of Grain.	Prince Edward Island.	Nova Scotia.	New Brunswick.	Quebec.	Ontario.	Manitoba.	North-west Territories.	British Columbia.
Oats	793	1,335	1,454	2,017	2,081	753	432	70

A NEW FEATURE IN THE GRAIN DISTRIBUTION.

During the past year a new feature has been introduced in connection with the distribution of seed grain. In sending out the 3-pound samples in the past it has scarcely been practicable to prescribe any particular size of plot on which these samples should be sown, each applicant has used his own judgment in that respect and there has been much variation in this particular. On this account no information could be obtained as to the relative yield per acre of the different sorts under trial. Under the new arrangement sufficient seed has been sent to sow one-tenth of an acre for which 8 pounds of oats and 10 pounds of barley or spring wheat have been supplied.

Fourteen of the best varieties of grain were chosen for this special purpose, six of oats, four of spring wheat and four of barley. As it was not practicable to send this quantity of grain to all applicants a select list of farmers was made by choosing from each constituency a few of those who had shown by their reports on the 3-pound samples that they were much interested in this important work. A circular was sent to each one with the names of the different sorts of grain to be sent out, and an opportunity afforded for each farmer to make choice of the variety he preferred. An active interest was taken in this subject by farmers in all parts of the Dominion and the total number who have taken part in the test is 4,320.

These samples were distributed by provinces as follows :—

Name of Grain.	P.E.I.	N.S.	N.B.	Que.	Ont.	Man.	N.W.T.	B.C.
Oats	64	209	240	587	744	130	113	50

Many samples have also been distributed from the branch experimental farms. Full particulars relating to these will be found in the reports of the Superintendents of the branch farms.

TESTS OF THE VITALITY OF GRAIN AND OTHER SEEDS FOR 1899.

During the season of 1899, 2,058 samples of seed grain and other seeds were tested chiefly for farmers, to ascertain the proportion which would germinate. Many of the samples received for test are much below the average and do not fairly represent the germinating power of the grain of average quality grown in different parts of the Dominion. The object in view in carrying on this work from year to year, is to give farmers the opportunity of having any samples which may be of doubtful vitality through injury during harvesting or storing, or from frost, thoroughly tested so that their value for seed purposes may be ascertained. Samples may be sent free through the mail and the quantity of grain sent should not be less than one ounce. The samples are tested and reported on free of charge and their proportion of vitality can usually be determined within a fortnight after they are received.

									33·86	77·25	41·63	166		

Rain or snow fell on 166 days during the 12 months.
Heaviest rainfall in 24 hours, 2·92 inches on July 11.
Heaviest snowfall in 24 hours, 10·00 inches on March 19.
It will be seen the highest temperature during the 12 months was 93·°7 on August 19.
The lowest temperature during the 12 months was −24·°1 on February 12.
During the growing season rain fell on 10 days in April, 13 days in May, 12 days in June, 17 days in July, 7 days in August and 17 days in September.
August shows the lowest number of days on which rain fell, viz., 7.
Rain or snow fell on 20 days in January.
Total precipitation during the 12 months, 41·63 inches, as compared with 37·17 inches during 1898.

WHAT THE EXPERIMENTAL FARMS HAVE DONE TO STIMULATE TREE PLANTING.

Experiments in tree planting were begun at all the Experimental Farms as soon as practicable after the sites selected were secured, but as the need for forest shelter is greater on the open plains in the North-west country, special attention has been given to this subject on the branch experimental farms at Brandon, Manitoba; and at Indian Head, in the North-west Territories.

CENTRAL EXPERIMENTAL FARM.

In 1888 forest tree planting was begun on this farm and two blocks of land devoted to this purpose. One of these 165 feet in width extends entirely across the west end of the farm, the other a narrower piece 65 feet in width, extends the full length of the north boundary. It was not practicable to complete this planting quickly, about 3,000 trees were planted in 1888, 7,700 in 1889 and the area of planting was added to from year to year until 1894 when the work was completed. These forest plantations contain about 20,800 trees including most of the more important timber trees which are hardy in this climate.

The objects in view in planting these forest belts at Ottawa were :—

1st. To ascertain the relative growth, in height and circumference of trunk of a number of different trees when planted at different distances apart. The distances chosen in this instance for trial were 5 feet by 5, 5 feet by 10 and 10 feet by 10.

2nd. To gain information as to the relative growth of these trees when planted in blocks of one sort, as compared with mixed clumps.

3rd. To find out how far farm crops located near tree belts will be influenced by the shelter they afford.

The pleasing effects produced on the landscape by blocks of trees when suitably grouped were not overlooked, but the main purpose has been to gain such practical information relating to the growth of the more important timber trees in this climate, as would be useful to those who may in future engage in timber growing in this country. Measurements of the annual growth of representative examples of the different sorts of

trees have been taken from time to time and the particulars published in the Reports of the Experimental Farms.

Forest trees sent to the branch experimental farms and to settlers for test.

In 1888, 2,800 young forest trees of twenty-eight sorts were sent from the Central Farm to the branch experimental farm at Nappan, Nova Scotia, to be tested in that climate, 20,000 were also sent to the branch farm at Indian Head, in the North-west Territories.

In 1889 some additional smaller supplies of trees were sent to Nappan, 12,000 trees and shrubs of 118 varieties were sent to the branch experimental farm at Brandon, Man., 15,000 to Indian Head, N.W.T., and 7,000, chiefly of the most valuable hard woods of the East, were sent to the branch experimental farm at Agassiz, in British Columbia.

Experimental gardens in which forest trees were to be tested, were laid out that year by the Canadian Pacific Railway at twenty-five different points on the main line between Moosejaw and Calgary. To each of these stations a bundle of well-rooted young forest trees was sent from the Central Experimental Farm, each package containing 175 trees of thirty-seven different species.

During this season 700 1-pound bags of tree seed were also distributed for test, consisting chiefly of box elder, green ash, butternut and black walnut. These were sent to farmers for planting, in different parts of the Dominion.

In 1890, 21,700 trees and shrubs were sent to the branch farm at Brandon, Man., 15,000 to Indian Head, N.W.T., and 8,000 to Agassiz, B.C.

To farmers—mainly to those residing in the Canadian North-west, there were sent that season 131,600 young forest trees and shrubs in 1,316 packages of 100 each, with instructions for planting and care. About 3,500 trees, in packages of about 150 each were also sent to the chief stations of the Mounted Police and to the Indian agencies in different parts of the North-west country.

In 1891 smaller supplies of trees and shrubs, including sorts not hitherto tested, were sent to the branch farms at Nappan, N.S., Brandon, Man., and Indian Head, N.W.T., and an additional supply of 7,284 to Agassiz, B.C.

The young forest trees sent by mail that year to settlers in Manitoba and the North-west Territories numbered 200,000. These were sent in 2,000 packages, each containing 100 trees.

During 1890 the native trees growing in the coulées and bluffs in the North-west bore an abundant crop of seeds, and with the aid of Indians and Half-breeds, nearly three tons of these were collected. These seeds were chiefly box elder and green ash, of which 4,053 1-pound bags were sent to applicants in Manitoba and the Territories. Limited distributions were also made at Brandon and Indian Head, and the remainder planted at these two farms in large seed beds.

In 1891 frosts destroyed most of the tree seeds, and very few could be obtained.

1892. In this and every subsequent season to the present, many additional species and varieties of trees and shrubs have been sent to each of the branch farms, new sorts which could not be procured earlier, including all those obtainable which were likely to prove hardy and useful in the different climates in which these farms are located.

This year 45,218 trees, a large proportion of which were evergreens, were sent in 983 packages by mail to North-west settlers for trial, and 91,800 cuttings of hardy poplars and willows were similarly distributed.

As no tree-seeds could be had in 1891, and the trees in 1892 were again well laden, nearly 3 tons more were collected in the autumn of that year.

In 1893, 83,000 young trees and cuttings were sent out to settlers, also 1,523 1-pound bags of tree seeds.

Since 1893, arrangements have been made to supply settlers in Manitoba as far as is practicable with young forest trees and tree seeds from the experimental farm at Brandon, and those residing in the Territories from the farm at Indian Head. Many applications, however, continue to be made to the Central Farm for tree seeds, and to meet this demand about 300 pounds have been obtained each year from the supplies collected at Brandon and Indian Head, and sent out from Ottawa.

The tree planting and tree distribution during the past twelve years at the Central Experimental Farm has aggregated as follows :--Planted at Ottawa, including forest belts, ornamental grounds, avenues, hedges and Arboretum, over 40,000 specimens. Total number of trees sent to the branch farms at Nappan, about 4,000 ; Brandon, 65,000 ; Indian Head, 70,000 ; Agassiz, 35,000.

The distribution from the Central Farm throughout the Dominion has been chiefly to settlers in the North-west. To these there have been sent during the same period about 560,000 young forest trees and cuttings, mostly in bundles of 100 each, and about 9,000 pounds (4½ tons) of tree seeds.

EXPERIMENTAL FARM, NAPPAN, N.S.

From the supplies of forest trees and shrubs sent to Nappan, much useful information has been gathered in reference to the hardiness and suitability of the different species to that climate. Permanent plantations have been made and a limited number of trees and shrubs have been sent for trial to farmers in different parts of the Maritime Provinces.

EXPERIMENTAL FARM, BRANDON, MAN.

A large proportion of the 65,000 trees and shrubs sent from the Central farm to Brandon, have been used for trial planting on that farm ; while many of the varieties have proved tender in that climate and a large number of trees have died, many others have been successfully grown. At the same time many thousand young trees have been raised from seed of native species and these have been set out in the plantations. The number of trees now growing on this branch farm in wind-breaks, avenues, hedges, Arboretum and nurseries is estimated at from 70,000 to 80,000. The Brandon farm has greatly aided tree growing in Manitoba by the practical object lessons it has given to the public in the various methods of tree planting adopted there. It has also distributed among the farmers of Manitoba young trees for test usually in bundles of 100 to each farmer and tree seeds in 1-pound bags as follows :—

In 1891	Trees and cuttings	20,500		
1892	" "	40,000		
1893	" "	60,000	Tree seeds 1-lb. bags....	400
1894	" "	46,800	" "	350
1895	" "	29,550	" "	226
1896	" "	77,700	" "	—-
1897	" "	90,600	" "	385
1898	" "	148,700	" "	165

Making in all 513,850 young forest trees and cuttings and 1,526 one pound bags of tree seeds sent out from this farm to the end of 1898.

EXPERIMENTAL FARM, INDIAN HEAD, N.W.T.

The branch farm at Indian Head has also done much to promote tree growing on the plains. To the 70,000 trees sent there from the Central Farm, there have been added a very large number of native trees grown from seed collected in the Territories, and it is estimated that there are now growing on that farm about 125,000 trees.

There has also been sent from the Indian Head farm to settlers in the Territories, young forest trees and cuttings in mail packages of about 100 each, and of tree seeds in 1-pound bags as follows :—

In 1890	trees and	cuttings	12,000				
1892	"	"	17,700				
1893	"	"	5,000	Tree seeds	1-lb. bags	....	200
1894	"	"	14,576	"	"	....	532
1895	"	"	19,350	"	"	....	360
1896	"	"	18,055	"	"	....	...
1897	"	"	16,796	"	"	....	1,460
1898	"	"	23,920	"	"	....	424
1899	"	"	59,700	"	"	....	381
			187,097				3,357

Making a total of 187,097 young forest trees and cuttings, and 3,357 one pound bags of tree seeds sent out during the period named.

EXPERIMENTAL FARM, AGASSIZ, B.C.

The 35,000 young trees sent to this farm—about two-thirds of which were of hard woods from the East—have been mostly used for planting on the Experimental Farm, chiefly on the sides of the low mountains forming part of the farm property. This has been done with the object of finding out whether these useful trees so valuable for their timber can be successfully grown in this climate. A limited distribution from among these has, however, been made to parties specially interested in tree growing in British Columbia. A few varieties including some of the more ornamental sorts have also been sent for planting on the grounds about the more important stations on the line of the Canadian Pacific Railway.

SUMMARY.

From the figures presented it will be seen that during the comparatively brief period of twelve years, since the experimental farms were founded, these useful institutions have laid the foundation for a great advancement in tree growing in Canada in the near future. There are now growing on the five Experimental Farms a grand total of about 245,000 trees. There has also been sent out from these farms during the period mentioned to individual lovers of trees in small lots of about 100 each 1,261,000 (more than $1\frac{1}{4}$ millions) young forest trees and cuttings and 14,000 pounds (7 tons) of tree seeds, every pound of which with reasonable care may be expected to produce from 500 to 800 young seedlings. The results of this work are now everywhere apparent. On homesteads in almost every part of Manitoba and the Territories there are small plantations of forest trees which furnish more or less shelter for the growing of garden vegetables, small fruits and flowers, also for buildings and stock and at the same time make the dwellings of the settlers more attractive and home like.

Since experience has shown that the box elder or Manitoba maple, the tree which has been most largely used in this work, begins to produce seed when about six or seven years old a large number of the trees early distributed must now have reached a seed-bearing age. On the western experimental farms a very large quantity of tree seeds are now ripened every season, on young trees planted since the farms were established, and from this time forward all over the country year after year as the number of seed bearing trees increase, immense and constantly increasing quantities of seed will be available and convenient for use, and thus an enormous impetus will be given to tree-growing especially on the North-west plains.

CORRESPONDENCE.

The following is a summary of the letters received and sent out at the Central Experimental Farm from November 30, 1898, to November 30, 1899, also the number of reports, bulletins and circulars forwarded by mail during the same period:—

—	Letters Received.	Letters Sent.
Director	42,653	19,325
Agriculturist	1,361	2,512
Horticulturist	1,318	1,346
Chemist	1,257	1,595
Entomologist and Botanist	2,495	2,320
Poultry Manager	1,507	1,092
Accountant	1,086	1,343
Totals	51,677	29,533

Circular letters sent, including circulars sent with samples of seed grain.......... 43,132
Number of reports and bulletins mailed.......... 152,826

SOME JOURNEYS UNDERTAKEN DURING THE YEAR.

EXPERIMENTAL FARM, NAPPAN, N.S.

Two visits were made to the Experimental Farm at Nappan, Nova Scotia, during 1899, the first early in May and the second during the month of October. On both these occasions careful inquiry was made regarding the work in progress. At both times the dairy herd was found in good condition and the cows were giving a good flow of milk. The steers which had been fed during the winter of 1898-9 were disposed of before my early visit was made, at good prices. Their presence during the feeding period had materially increased the quantity of barn-yard manure available for the ensuing crops. An additional area of land was cleared during the winter of 1898–9, which has since been utilized as pasture for cattle. The water supply provided last year, drawn from springs on the rear end of the farm, has proved an abundant one, ample for the stock barns as well as for the dwellings on the farm. The quality of the water is excellent.

In October I found the crops all gathered with the exception of the turnips, which were then being brought in. Nothwithstanding the cold and backward spring which had delayed seeding, most of the grain crops had turned out remarkably well. The oats and wheat both gave yields considerably above the average. The straw was strong and bright and the grain well developed and plump. The root crop was also good.

The fruit trees in the orchards had made fair growth, and all sorts of small fruits had done well. The hedges, shelter belts and plantations of shrubs and trees were all in a thriving condition and had made satisfactory progress.

ANNUAL MEETING OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

About the middle of August I visited Columbus, Ohio, where I had the privilege of attending the meetings of the American Association for the Advancement of Science, also the meetings of the Society for the Promotion of Scientific Agriculture. The attendance was large, and distinguished men representing every branch of science were there, and many valuable contributions were made to our knowledge in the papers which

were presented. The facts submitted relating to the progress of agriculture were especially valuable to those interested in that subject and elicited much discussion and comment. The meetings were held in the large and commodious buildings of the University of Ohio, and opportunities were thus afforded of visiting the museums rich in botanical, entomological and other specimens and of examining the large collection of trees and shrubs on the University grounds. The week spent there was a profitable one.

MINNESOTA EXPERIMENT STATION.

Journeying westward, two days were given to an examination of the work in progress at the Minnesota Experiment Station at St. Anthony's Park near Minneapolis. Much advancement has been made since my visit there in 1894. Many new buildings have been erected and the grounds very much improved by the growth which has taken place in the trees and shrubs as well as by additional planting.

Although the grain crops had all been harvested, there was much to interest one in the plantations of small and large fruits as well as in ornamental trees and shrubs. A large collection of improved varieties of American plums has been brought together there and under the guidance of the Horticulturist, I had ample opportunities for testing the relative merits of a number of different sorts which were then in process of ripening. Many varieties of the hardier sorts of Russian apples were being tried with a considerable degree of success.

In company with the assistant agriculturist, I also had the privilege of visiting some of the large flour mills in Minneapolis, and of inquiring into the newer methods in use there of determining the relative value of the different sorts of wheat when converted into flour.

NORTH DAKOTA EXPERIMENT STATION.

The experiment station of North Dakota was next visited, which is located near Fargo. At the outset the conditions and surroundings of this institution were much like those of the experimental farm at Indian Head. Both originally were started on bare prairie lands and much attention has been given to tree planting for shelter and ornament. The progress made at Indian Head has been much more rapid and the field of work covered more extended than at Fargo. There were, however, many things of interest to be seen and inquired into, which made the day spent there under the kind guidance of the station officials both pleasant and profitable.

EXPERIMENTAL FARM, BRANDON, MAN.

Leaving Fargo, the journey was continued to the branch farm at Brandon. Although too late to see many of the standing crops most of the grain from the experimental plots was still in stook. Notwithstanding that the season had opened unfavourably and that wet weather had delayed seeding in the spring, the grain crops at this farm were excellent and the yield in some cases very large. This was notably the case with oats and wheat. Some of the most productive sorts of oats had given from 100 to 110 bushels per acre, and some of the best of the wheats from 30 to 45 bushels per acre. Pease had yielded good crops. Awnless Brome grass and some native grasses gave remarkably good returns, the yields of field roots and potatoes were about an average, while Indian corn and Millets gave lighter crops than usual.

The stock was in a healthy state, the implements well cared for and the progress of the farm work in a general way very satisfactory. The small fruit plantations had done well and the ornamental trees, shrubs and hedges had made excellent growth. The flower beds about the buildings were gay with bloom of varied hues, and were proving very attractive to a large and increasing circle of visitors.

EXPERIMENTAL FARM, INDIAN HEAD, N.W.T.

This farm was next visited, and the various branches of work conducted there inquired into. The horses, cattle, swine and poultry were all in good condition and gave evidence of careful handling. The barns were well stored with excellent hay, the product of the fields of Awnless Brome grass and native Western Rye grass on the farm. Owing to the unusually favourable conditions of moisture in 1899, the hay crop has been very good.

The spring was very wet which made seeding unusually late and after it was fairly begun its progress was several times interrupted by heavy storms. With abundance of moisture and a very rich soil the growth of straw was rank, and in some districts this delayed the ripening of the grain so that some of it was injured by frost before it was fully matured. At the Indian Head farm, however, all the cereal crops gave a bountiful return. Most of the best varieties of wheat gave from 30 to 38 bushels per acre, oats from 80 to 95 bushels, and barley from 55 to 65 bushels per acre.

Good crops of field roots have also been produced, but the crop of Indian corn has been light. The shelter belts and other tree plantations have made remarkable growth and the wood ripened fairly well before winter set in. Many of the early planted trees on this farm are now yielding an abundance of seed which is gathered each season and distributed among farmers who apply for it in different parts of the Territories.

WESTWARD THROUGH THE CROW'S NEST PASS.

Proceeding westward a trip was made through the Crow's Nest Pass where the scenery although not nearly so grand as on the main line of the Canadian Pacific Railway is very varied and interesting. Wonderful development is going on in that portion of the Dominion. The output of coal is enormous and the growth of some of the towns phenomenal. At Fernie, on the western slope of the Rocky Mountains, a place but little more than a year old there is a population of nearly a thousand people. The coal there is specially adapted to the making of coke of excellent quality for smelting and at the time of my visit 150 coke ovens were in constant use, turning out 1,200 tons of coke per week, while 50 additional ovens were in course of construction. The advent of the railway by which large and valuable coal deposits have been reached has been an important factor in the progress of mining industry in that region, which is advancing by leaps and bounds. Cranbrook is an older and more populous town in which a large business is done.

All along the route through the Kootenay country, the district is so mountainous and rocky that there does not appear to be much land available for agricultural purposes. From the few crops visible from the trains and the fruit trees seen growing in the gardens in some of the older towns, it was evident that in many parts of that country the climate is well adapted to the growing of agricultural crops and also of fruits of high quality. Some very fine pears, apples and plums were seen on the trees in some of the older gardens. A day was spent at Nelson and another at Rossland, both of which are now important and interesting places. In both these towns, mining is being actively pushed and the daily output of ore is very large. At Rossland the formation of the mountains is such as to resemble a large basin and part way up the steep sides of this basin at an elevation of about 3,000 feet the town is built. The railway climbs to this height by a succession of steep grades. Although only four years old this town has a population of several thousand and business of all sorts seemed to be very brisk. On the way to Rossland, Trail was passed, where there is a very large smelter which was then being worked to the fullest capacity, and the valuable metals were extracted from an enormous quantity of ore every week. On the way up the Arrow Lakes from Robson to Revelstoke, the new line of railway recently built to the eastern part of the boundary country was seen. This runs along the sides of the mountains which skirt the margin of the Arrow Lakes for about 30 miles, then turning south-westerly up the valley of Kettle Creek, is soon lost to view. Taking a sleeper from Revelstoke the journey was made to Agassiz, B.C., by about ten the following morning.

EXPERIMENTAL FARM, AGASSIZ, B.C.

The work on this branch experimental farm is making good progress. An additional area of land is cleared every year and the portions devoted to orchards and field crops are being gradually enlarged. About 140 acres are now under cultivation nearly one-half of which has been planted with fruit. A very large number of varieties of fruit have been brought together on this farm from many different countries, and as these trees come to a bearing age much useful information is gained from year to year as to the sorts best suited to the climate and most profitable to the grower.

The season of 1899 has been a most unfavourable one here for fruit. The spring was very late and rain was so frequent, with dull weather intervening all through the blossoming period that very little fruit set. Some varieties, however, of apples and plums and a few of the pears bore a partial crop, but the total yield was very disappointing. The crops of hay and oats were good, barley also has given a fair yield. The quantity of wheat grown in this province is small, but the crop was about an average one. The season was unusually cool as well as wet, which was unfavourable for Indian corn and this crop was light. Field roots gave satisfactory returns. The hedges, avenues and plantations of forest and ornamental trees had made excellent growth.

A VISIT TO THE DOUKHOBORS.

On returning east a trip was taken up the Manitoba and North-western railway from Portage la Prairie to Yorkton, and thence by vehicle nearly 100 miles to the north trail of the Swan River near Thunder Hill. Journeying then eastward for many miles the Swan was again forded and travel continued on the south trail until the Dauphin Railway was reached. During this drive of about 150 miles, many villages of the Doukhobors were passed and inquiries made as to their progress in these new settlements, in providing shelter and food for the winter and in preparing land for crop next season. At the time of my visit nearly all the able-bodied men were away from the villages working on the railways or assisting the settlers within reach in their harvesting and threshing, thus earning money to buy supplies for the winter, while some of the older men and the boys with the help of a number of the strong and active women were building houses and preparing land for crop next year. They are a very industrious people and appear to be well satisfied with the country. Most of the land in their settlements is of good quality and the locations they have chosen are more or less wooded, affording convenient supplies for building operations, and for firewood. They are all vegetarians and will not eat animal food as they consider it a sin to kill, many of them, however, will eat fish, and some of their villages are located near small lakes in which fish are abundant. They like butter, cheese and eggs, but as yet can get very little of these useful concentrated foods, as their stock of cows is so small as to give them but a meagre supply of milk, and they have very few fowls. At the time of my visit they were subsisting chiefly on dry bread made from a low grade of flour, with soup made by boiling a mixture of flour and water, with vegetables such as cabbages, onions and beets and in some instances potatoes of which they are very fond. In most of the villages considerable quantities of vegetables have been grown, but not nearly enough for the requirements of the people for the winter.

HOW THEY LIVE.

The houses of the Doukhobors are substantially built of logs, and roofed with poles, on which prairie sod about 4 inches thick is laid and the interstices filled with fine earth. The sides of the houses are well plastered on the outside with clay mixed with cut straw or hay and sometimes on the inside also with the same material. The furniture in the houses is all of their own make and consists of a few rough stools to sit on, and higher benches which serve as tables. The beds are made of a series of poplar poles about 6 feet long and 3 or 4 inches in diameter, placed close together along

one or both sides of the house, with the ends to the wall. On these some hay is placed and over this a piece of thick felt. The people recline on this structure with their heads to the wall, feet outwards using such bed clothes as they can command. A few have feather beds and curtains to divide the sleeping places into compartments. Most of the houses consist of one large room for living, cooking, eating and sleeping. The aim is to have in all their villages a house for each family, and these houses were being erected at varying distances in two rows with a wide street between them. Although new houses are going up rapidly in every village, the absence of the able bodied men necessarily interferes with the progress of this work, and in some of the villages at that time each house was occupied by from 10 to 20 people and in a few instances the inmates numbered from 25 to 40.

In these densely populated buildings the beds are arranged in a double tier the upper one being reached by a ladder. In each house there is a Russian oven similar to those used by the Mennonites in Manitoba, which serves for the warming of the building and cooking the food.

These people seem very contented and although in many instances conditions were met with, which would with us be regarded as cases of hardship, not a word of complaint was heard from any of them. They are honest, truthful and hard working, cleanly in their habits and use neither liquor nor tobacco. Being vegetarians they are at present at a disadvantage as compared with other settlers, as there is much game about their settlements with which they could easily supplement their vegetable diet with great advantage. They appear, however, to be very strong and hardy and will I believe prove a very useful class of people in the districts in which they are settled, and will soon form prosperous communities which will aid much in the development of the country. They may, however, need some assistance for a time until they can earn enough, together with the produce they can get from their land to sustain them.

THE RETURN JOURNEY.

The return was made by the Canadian Northern Railway which runs through the Dauphin country from Gladstone to Swan River. The Manitoba and North-western and the Canadian Northern are both substantially built roads, which connect with the main line of the Canadian Pacific at Portage la Prairie. Each line runs through portions of the country where much of the land is of excellent quality and the conditions are favourable for mixed farming. Settlement is proceeding rapidly and traffic is increasing and the returns are improving from year to year.

THE PARIS EXPOSITION.

Much work has been done at all the Experimental Farms in providing choice material, both in grain and fruit, for the forthcoming Paris Exposition. A large number of varieties of cereals and other agricultural products have been put up in suitable form for display both in straw and as cleaned grain.

The Central Experimental Farm has contributed 18 cases of cereals and 224 bottles of fruits preserved in antiseptic fluids, and the branch farm at Nappan, Nova Scotia, 7 boxes of grain and 214 bottles of fruit. The farm at Brandon, Man., has sent 8 cases of cereals and 81 bottles of small fruits and vegetables; Indian Head, N.W.T., has forwarded 9 boxes and 25 bags of grain and 123 bottles of vegetables and small fruits, while from Agassiz there has been sent 5 cases of grain, 188 bottles of preserved fruit and 17 cases of fresh fruit. The Experimental Farms have thus contributed materially to the magnificent display of agricultural and horticultural products which will be made by Canada on this important occasion.

ACKNOWLEDGMENTS.

To the Director of the Royal Gardens, Kew, England, grateful acknowledgments are due for another valuable collection of the seeds of trees, shrubs and plants from

many countries. Also to the Director of the Arnold Arboretum, Jamaica Plains, Mass., for seeds of rare and promising varieties. To the United States Department of Agriculture at Washington, I am indebted for a number of differert sorts of cereals, and to Prof. John Macoun, Naturalist, of the Geological and Natural History Survey, and to Mr. J. M. Macoun, Assistant Naturalist, my thanks are due for seeds of many interesting native species, gathered in different parts of Canada.

The faithful services rendered by all the officers at the Central and Branch Experimental Farms, and their earnest co-operation in carrying out the many lines of experimental work planned, are gratefully acknowledged.

My thanks are also due to those members of the staff who have rendered most efficient help in those branches of the work of which I have had personal charge: to the Horticulturist, Mr. W. T. Macoun, who has supervised the labour given to the lawns, and to the trees and shrubs planted on the ornamental grounds: to the Farm Foreman, Mr. John Fixter, who has carefully watched over the different branches of the work, taken special charge of the fertilized plots, and aided me much by his practical suggestions: to Mr. Harry Fixter, who has managed the work connected with the experimental plots of cereals, fodder crops and field roots, and has taken records of the growth and yield of all the varieties grown in the uniform test plots, to whom I am also indebted for the careful management of the many details connected with the distribution of samples of seed grain. Careful work has also been done by Mr. Wm. Ellis, in testing the vitality of seeds, in the management of the green house plants, in the propagation of many useful and ornamental species and in the taking of the meteorological records. The employees also of all the farms, in every branch of work, have shown commendable care, and have faithfully discharged their respective duties.

WM. SAUNDERS,

Director Experimental Farms.

REPORT OF THE AGRICULTURIST.

(J. H. Grisdale, B. Agr.)

Dr. Wm. Saunders,
Director Dominion Experimental Farms,
Ottawa.

Sir,—I have the honour to submit herewith reports on (1) Horses, (2) Pure-bred Breeding Stock. (3) The Dairy Herd. (4) Experiments in Beef Production. (5) Experiments in Pork Production. (6) Sheep. (7) The Farm Dairy, and (8) The 200 Acre Farm, rotation, methods of cultivation and crops thereon.

I have addressed meetings at Merivale, Shawville, Rockland, Kingston, Eastern Ontario Dairymen's Association, St. Jerome, Quebec Dairymen's Association, London, Leicester Breeders' Association, Mattawa, Carleton Place and Almonte.

I am indebted to John Fixter, farm foreman, and to R. R. Elliott, herdsman, for particularly valuable assistance, both in carrying on the work reported upon and in the preparation of the submitted report.

I have the honour to be, sir,
Your obedient servant,
J. H. GRISDALE,
Agriculturist

HORSES.

There are in the farm stables at present thirteen horses. A number of these are rather old animals and will need to be replaced at an early date. During the year two were sold and a young team bought to replace them.

Three of the above horses are required for the omnibus, which runs from the farm to the city, making three trips daily. One is used as a driver, and one for general jobbing.

The remaining eight horses constitute the teams for general work upon the farm, in the garden and orchards, upon the lawns and in the Arboretum, as well as for cartage. This number of horses has during the past year proven to be very far short of the requirements as detailed above, and it has been found necessary to hire additional teams.

PURE-BRED BREEDING CATTLE.

There are on the farm at present representatives of three breeds of cattle: Ayrshires, Guernseys, and Shorthorns. They are as follows:—

Ayrshires;

1 bull, "Matchless Again," [8,757]....................2 years old.
1 heifer, "Darling"..........................1 year 8 mos. old.

Guernseys:

1 bull, "Wedgewood," [5,113]........................5 years old.
2 bulls..1 year old.
1 heifer...1 year 9 mos.

Shorthorns:

1 bull, "Royal Don," [24,639]........ ....4 years old.

It is proposed to secure a few more females of each breed represented, and maintain small herds of these breeds.

The bulls are used upon our grade cattle, and small graded herds of each breed are to be built up. The services of the stock bulls are available to farmers upon payment of a moderate charge.

DAIRY CATTLE.

The herd of dairy cattle consists of twenty-nine females all told. They are:—

Canadian grades	5
Yearlings	5
Ayrshire and other grades	15
Calves	4

During the year no experimental work in feeding has been conducted, save that the ration being fed on my taking charge has been allowed to continue for a year, as the basis of some experimental work in feeding for increased milk production.

During the year some of the older, and less valuable, and a few younger, rather inferior, cattle have been sold to the butcher.

The dairy cows have been fed a roughage ration, of corn ensilage, 35 pounds, chaff, 3 pounds, hay, 5 pounds, and mangels, 20 pounds daily; some receiving slightly more, others, somewhat less, according to requirements. The grain ration has been from 2 to 8 pounds per diem of a mixture of equal parts of oats, pease, barley and bran. The cows when dry have received the same roughage ration with no meal, and the heifers have been fed similarly.

During the year, twenty-five cows have been milked, the number of days in lactation varying from 49 to 365, or an average of 284 days per cow. The total milk sold was 135,346 pounds, which, valued at current factory prices, amounted to $1,280.47. This makes an average of $51.22 per cow.

Valuing our feed stuffs as follows:—

Bran and meal	$15 00	per ton.
Ensilage	2 00	"
Roots (mangels)	2 00	"
Clover hay	5 00	"
Chaff	3 00	"
Pasture	2 00	per month per cow.
Dry cows	2 00	"

The cost of maintaining our herd for the year was $1,030.51 or an average of $41.22 per cow. This leaves a net average profit of $10 per cow.

The past summer has been a most trying one on our dairy herd, since it was impossible to protect them properly from sun and flies, owing to lack of shade trees in the pasture and the practical impossibility of stabling them at will during the season of excessive heat and many flies, owing to insufficient fencing.

STEERS.

During the year a number of steers have been fed experimentally to test the comparative values of certain rations, a particular description of the composition of which, and the plan of feeding the steers, follows:

Thirty-two steers were bought in October, 1898. These were fed a uniform ration of roots 25 pounds, ensilage 50 pounds, hay 5 pounds, straw 5 pounds, at the rate of 50 pounds each daily.

On December 1, they were divided into eight lots of four each. Following are statements of the treatment of each group, with data obtained in the sixteen weeks during which the experiment was continued, viz., from December 1, 1898, to March 23, 1899. On March 23, the steers were again put on a uniform roughage ration of ensilage 33 pounds, hay 8 pounds, roots 12 pounds, 6 pounds meal, equal parts oats, pease, and barley, and were kept on this ration till April 4. On this date the roots were finished and 12 to 15 pounds of ensilage was substituted. This ration was maintained till May 22, when the lot was sold at $4.60 per cwt. live weight.

Lot 1 was fed on a roughage ration of 46 pounds per steer daily, made up of the following feeds in the given proportion: Corn ensilage 50 pounds, roots 25 pounds, hay, mixed (cut) 5 pounds, oat straw (cut) 5 pounds.

During the first four weeks period no meal was fed. During the second four weeks period 2 pounds meal, equal parts oats, pease, and barley was fed daily per head. During the third four weeks period 4 pounds meal was fed daily per head. During the fourth period of four weeks 6 pounds meal was fed per head.

Lot 1.	Starting Weight.	Final Weight.	No. of Days Fed.	Total Gain.	Daily Rate of Gain.	Total Cost of Feed.	Cost of 1 Pound Gain.
4 Steers.....	4,075	4,680	112	605	1·35	$35.41	5.86 cts.

This lot cost to feed during November, $3.86, December 1 to March 23, $35.41, and from March 23 to May 22, $28.70, making a total cost of $67.97.

The net proceeds from this lot were.......	$ 217 35
Their gross cost	197 67
A net gain of..	$ 19 68

Lot 2 was fed a roughage ration of 46 pounds per diem, made up of the following feeds in the given proportion. Corn ensilage 50 pounds, roots 25 pounds, hay, mixed (cut) 5 pounds, oat straw (cut) 5 pounds. During the first four weeks no meal was fed. During the second four weeks period 2 pounds meal (half cotton seed meal and half pease, oats and barley) was fed. During the third period of four weeks 4 pounds meal (half cotton seed and half pease, oats and barley) was fed. During the fourth period of four weeks 6 pounds of meal was fed, 2 pounds cotton seed meal and 4 pounds meal, equal parts pease, oats, barley, in each case to each animal daily.

Lot 2.	Starting Weight.	Final Weight.	No. of Days Fed.	Total Gain,	Daily Rate of Gain.	Total Cost of Feed.	Cost of 1 Pound Gain.
4 Steers.....	4,080	4,648	112	568	1·27	$36.89	6·50 cts.

This lot cost to feed during November, $3.86, December 1 to March 23, $36.89, and from March 23 to May 22, $28.70, making a total cost of $69.45 for feed.

The net proceeds from this lot were....................	$217 78
The gross cost was.....................................	199 15
A net gain of..	$18 63

Lot 3 was fed a roughage ration of 46 pounds per diem, made up of the following feeds in the given proportion :—Corn ensilage, 50 pounds ; roots, 25 pounds; hay, mixed

(cut) 5 pounds; oat straw (cut) 5 pounds. During the first period of four weeks no meal was fed. During the second four weeks period 2 pounds meal (half oil cake and half pease, oats and barley equal parts) was fed. During the third four weeks period 4 pounds of the same mixture was fed to each animal daily. During the fourth four weeks period 6 pounds per steer was fed of a mixture of 2 pounds oil meal to 4 pounds of a mixture of oats, pease and barley equal parts.

Lot 3.	Starting Weight.	Final Weight	No. of Days Fed.	Total Gain.	Daily Rate of Gain.	Total Cost of Feed.	Cost 1 lb. Gain.
4 Steers	4,080	4,720	112	640	1·43	$37.28	5·82 cts.

This lot cost to feed during November, $3.86, December 1 to March 23, $37.28, and from March 23 to May 22, $28.70, making a total cost of $69.84 for feed.

The net proceeds for this lot were	$214 59
The gross cost was	200 70
A net gain of	$13.89

Lot 4 was fed a roughage ration of 46 pounds per diem, made up of the following feeds in the given proportion :—Corn ensilage, 50 pounds ; roots, 25 pounds ; hay, mixed (cut) 5 pounds ; oat straw (cut) 5 pounds. During the first period of four weeks no meal was fed. During the second four weeks period 2 pounds, meal (half corn and half pease, oats and barley, equal parts) was fed daily per steer. During the third period of four weeks 4 pounds of the same mixture was fed, aud 6 pounds during the fourth four weeks period.

Lot 4.	Starting Weight.	Final Weight.	No. of Days Fed.	Total Gain.	Daily Rate of Gain.	Total Cost o Feed.	Cost 1 lb. Gain.
4 Steers.....	4,090	4,747	112	657	1·47	$35 60	5·42 cts.

This lot cost to feed during November $3.86, December 1 to March 23, $35.60, and from March 23 to May 22, $28.70, making a total cost of $68.16 for feed.

The net proceeds for this lot were	$219 37
The gross cost was	199 51
A net gain of	$19 86

Lot 5 was fed a roughage ration of 46 pounds per diem, made up of the following feeds in the given proportion :—Corn ensilage, 50 pounds ; roots, 25 pounds ; hay, mixed (cut) 5 pounds ; oat straw (cut) 5 pounds. During the first period of four weeks no meal was fed. During the second four weeks period 3 pounds of meal (half corn and half bran) was fed each steer daily. During the third four weeks period 4 pounds of the same mixture was the daily ration per steer, and 6 pounds daily per steer during the fourth four weeks period.

Lot 5.	Starting weight.	Final weight.	No. of days fed.	Total gain.	Daily rate of gain.	Total cost of feed.	Cost of one pound gain.	Cost to feed 1 steer 1 day.
4 Steers	4,095	4,715	112	615	1·38	$34.82	5·66 cts.	7·77 cts.

Ayrshire Heifer 'Darling,' (yearling)—Central Experimental Farm, Ottawa.

Guernsey Bull 'Wedgewood,' 5 years old, Central Experimental Farm, Ottawa.

Leicester Ram 'Laurier,' (Shearling.)—Central Experimental Farm, Ottawa

This lot cost to feed during November, $3.86, December 1 to March 23, $34.82, and from March 23 to May 22, $28.70, making a total cost of $67.38 for feed.

The net proceeds for this lot were	$ 218 13
The gross cost was	198 73
A net gain of	$ 19·40

Lot 6 was fed a roughage ration of 46 pounds per diem, made up of the following feeds in the given proportion :—Corn ensilage, 50 pounds ; roots, 25 pounds ; hay, mixed (cut) 5 pounds ; oat straw (cut) 5 pounds. During the first period of four weeks no meal was fed. During the second four weeks period 2 pounds of meal (equal parts cotton seed meal, oil cake, cornmeal and bran) was fed per steer daily. During the third four weeks period 4 pounds of the same mixture, and 6 pounds during the fourth four weeks period was fed daily to each steer.

Lot 6.	Starting weight.	Final weight.	No. of days fed.	Total gain.	Daily rate of gain.	Total cost of feed.	Cost of one pound gain.	Cost to feed 1 steer 1 day.
4 Steers........	4,095	4,655	112	560	1·25	$35.08	6·26 cts.	7·83 cts.

This lot cost to feed during November, $3.86, December 1 to March 23, $35.08, and from March 23 to May 22, $28.70, making a total cost of $67.64 for feed.

The net proceeds for this lot were	$215 69
The gross cost was	198 00
A net profit of	$ 17 69

Lot 7 was fed a roughage ration of 46 pounds per diem per steer, made up of the following feed in the given proportion :—Corn meal 50 pounds; hay, mixed (cut) 5 pounds; oat straw (cut) 5 pounds. During the first period of four weeks no meal was fed. During the second period 2 pounds meal (half corn meal and half pease, oats and barley equal parts) was fed to each animal daily. During the third four weeks period 4 pounds of the same mixture, and 6 pounds during the fourth four weeks period was fed daily to each steer.

Lot 7.	Starting weight.	Final weight.	No. of days fed.	Total gain.	Daily rate of gain.	Total cost of feed.	Cost of one pound gain.	Cost to feed 1 steer 1 day.
4 Steers......	4,100	4,685	112	585	1·30	$32.07	5·46 cts.	7·16 cts.

This lot cost to feed during November, $3.86, December 1 to March 23, $32.07, and from March 23 to May 22, $28.70, making a total of $64.63 for feed.

The net proceeds for this lot were	$217 85
The gross cost was	194 50
A net gain of	$ 23 35

Lot 8 was fed night and morning with 30 pounds of a mixture of corn ensilage and oat straw in the proportion of 10 to 1, while at noon they received 25 pounds roots and 5 pounds log hay. During the first four weeks period no meal was fed. During the second period of four weeks 1 pound meal (half cotton seed meal and half oats, pease and

barley) was fed to each steer daily. During the third four weeks period 2 pounds of the same mixture, and 4 pounds during the fourth four weeks period was fed daily to each steer.

Lot 8.	Starting weight.	Final weight.	No. of days fed.	Total gain.	Daily rate of gain.	Total cost of feed.	Cost of 1 lb.	Average cost to feed steer 1 day.
4 Steers.	4,115	4,725	112	610	1·36	$36.87	6·04 cts.	8·23 cts.

This lot cost to feed during November, $3.86, December 1 to March 23, $36.87, and from March 23 to May 22, $28.70, making a total cost of $69.43.

The net proceeds of this lot were	$ 216 00
The gross cost was	200 78
A net gain of	$15 22

SPRING STEER FEEDING.

On February 21, twenty steers were bought in, and on March 29, nine more were purchased. These steers were fed on ensilage and long hay for roughage and a meal ration of oats, pease and barley. The twenty-nine steers made a gain of 5,825 pounds during the period fed, or a daily average gain of 2·06 pounds.

Cost of steers	$ 874 00
Cost of meal consumed	80 00
Value of roughage fed	125 60
Gross cost	$ 1,079 60
Net proceeds of sale	$ 1,094 34
	1,079 60
Net gain	$14 74

These lots of steers were fed for the special purpose of making a market for a large amount of ensilage and clover hay which would otherwise have been on hand during the summer, and would thus have lost considerably in value, as well as been an inconvenience. By thus feeding this roughage, considerable valuable and necessary manure is at our command.

EXPERIMENTS FOR 1900.

During the past autumn 77 steers have been purchased. The average cost has been $3.47 per cwt. live weight. These are being fed experimentally, the chief objects in view being (1) a dehorning test, (2) a comparison of three year olds, two year olds and yearlings as economical beef producers, and (3) a test of tied versus loose fed steers as economical flesh producers.

DEHORNING STEERS.

To gain some information as to the exact cost of dehorning steers in loss of flesh due to excitement, loss of blood, and pain caused by operation, an experiment along this line has been conducted.

The steers, twenty-two in number, all two year old, were placed as follows:

Lots. Nos. 2 and 3, of nine each, were tied in two rows (1 lot in each) facing each other. Lot No. 4, of nine steers, was loose in a box stall 36 by 15 ft.; Lot No. 6, of nine steers, was tied in a separate building; and Lot No. 7, of six steers, was loose in a box stall 24 by 14 ft.

Lots. Nos. 3 and 4, and half of Lot No. 7 were dehorned November 16. The saw was used on six of them, three in each of Lots. Nos. 3 and 4; the Keystone Clipper on six more, three in each of Lots. Nos. 3 and 4; the large double-action, straight cut clipper on six more, three in each of Lots. Nos. 3 and 4; and the single-action straight cut on three in Lot No. 7.

The dehorned cattle, as well as those in Lot No. 2, were weighed daily for a time. The following are the gross weights recorded:—

Lot.	Treatment.	Gross Weight of Lots.					
		November.					December.
		16	17	18	20	28	5
2	Tied, not dehorned facing 3.....	8,905	8,715	8,525	8,595	8,580	8,915
3	Tied, dehorned..............	8,655	8,470	8,370	8,360	8,415	8,630
4	Loose, dehorned..............	8,340	8,300	8,270	8,315	8,400	8,540
6	Tied, not dehorned...........	7,700	Not	Not	Not	7,825	7,865
7	3 dehorned steers loose with	2,420	weighed.	weighed.	weighed.	2,350	2,395
7	3 hornless steers	2,730	"	"	"	2,752	2,795

It will be observed that Lot No. 2, though not dehorned, lost in weight. This might be ascribed to their position facing Lot No. 3, as they suffered from excitement as much almost as the dehorned lot.

Lots Nos. 2 and 3, it will be observed, recovered their original weight about the same date.

Lot No. 4, took only six days to recover from the operation, for on November 21, they weighed 8,345 pounds, 5 pounds above their weight on November 10.

The check lot in the separate stable, designated Lot No. 6, was not weighed daily, but made slow, steady progress.

The dehorned steers in Lot No. 7, lost considerable weight and did not finally recover till December 20. This was doubtless due to their being loose with the other steers, which were not sore, and besides were larger steers. These latter, it will be observed, made some gain.

While no positive conclusions may be reached as to the exact cost of dehorning, it would appear from a comparison of Lot No. 2, with Lot No. 4; of Lot No. 4, with Lot No. 6; and of dehorned part of Lot No. 7 with hornless part of the same lot, that no great setback is suffered by steers from this operation. It was observed that nervous, irritable individual animals were much more affected than sluggish, phlegmatic ones. It must be remembered that all these steers had just been stabled, and so would, of course be making very little progress in any case during this period.

No great difference was observable in the effect of the different instruments used in dehorning, save that there was practically no blood lost where the saw was used.

One anial in lot No. 3, dehorned with the Keystone Clippers lost a great deal of blood, but inno other case was there any serious bleeding.

STEER CALVES

An exeriment with calves is being incepted. Ten calves, Shorthorn grades, divided into two eqal lots, will be fed: Lot 1, a good growing ration; Lot 2, a ration sufficient

to keep the calves in high condition from the first. It is desired to ascertain (1) the comparative economy of these systems, and (2) the actual cost of raising a steer to the age of two years, (*a*) ready for the block, (*b*) ready to feed, under such conditions as maintain in this latitude.

SHEEP.

In April, it was decided to introduce sheep upon the farm, and the following is the sum of the flocks at present.

Leicesters:	1 ram	1 year old.
	1 ewe	2 years.
	3 ewes	shearlings.
	3 lambs	8 months.
Shropshires:	1 ram	1 year old.
	4 ewes	shearlings.
	4 "	lambs (8 mos.)
Grades:	10 "	shearlings.
	8 "	lambs (8 mos.)

Two of the Shropshire shearlings were imported from England, the remaining pure-breds, both Shropshire and Leicester, were bought in Canada. The grades were secured from a city butcher, and were selected as the average of large lots intended for the block.

Since the space available for sheep is at present very limited, it was possible to keep only two flocks. The Shropshire and Leicester were accordingly selected as being fairly typical representatives of the short and long woolled breeds.

It is hoped that a few more breeds may in time be introduced.

In most parts of Canada the sheep bred by the average farmer are of a very inferior class. Further, in many sections, especially suited for the profitable production of mutton and wool, very few or no sheep are raised, owing, in many cases, to uncertainty as to the possibilities of this class of animals as money-makers. It is proposed, therefore, to show, by the use of pure-bred rams upon grade ewes, the advisability of using good sires to improve our flocks, and the superiority of well-graded flocks over scrubs as money producers, as well as to help the introduction of this class of live stock into more general favour.

It is desired also to gain some data as to the cost of fitting lambs and shearlings for our markets, foreign and domestic, as well as to study the quality of mutton best suited for the same.

The study of the value of sheep as enrichers of the soil will also enter into this work, and their value as weed destroyers be tested to a certain extent.

PIGS.

At present the stock of breeding pigs consists of the following pure-bred animals :—

Large Improved Yorkshires	1 boar	3 years old.
	1 sow	1 year "
	2 sows	9 months old.
Improved Berkshires	1 boar	1½ years "
	1 sow	3 " "
	1 "	1½ " "
Tamworths	1 boar	2 " "
	1 sow	3 " "
Poland Chinas	1 boar	2 " "
	1 sow	1½ " "
	1 "	8 months

There are besides nineteen cross-bred pigs of our own breeding about three months old, which are to be fed off experimentally.

BREEDING

For some years past experimental work has been carried on in cross-breeding. This line, it is now intended to discontinue for a time, and its place will be taken by work in "grading up."

EXPERIMENTAL FEEDING.

During the year a number of swine have been fed experimentally for the purpose of: (*a*) discovering the cause or causes of "soft" pork; (*b*) contrasting ground with whole grain as an economical pork producer; (*c*) studying the economy of a limited grain ration as compared with an unlimited one; and (*d*) studying the effect of "finishing" on rape and roots upon: (1) economy of pork production; (2) quality of flesh.

Part of the data from (*a*) and the whole of that from (*b*) and (*c*) have appeared in Bulletin No. 33, recently issued by this division.

An extensive experiment for the purpose of discovering the cause or causes of "soft" pork was begun in July, and is still in progress. This will be reported upon later.

Below are the details of, and data obtained from an experiment recently completed.

FEEDING PIGS ON RAPE.

On August 2, 1899, two lots of six pigs each were placed on a rape plot of about $\frac{1}{4}$ acre. This rape had been sowed in drill on May 20, but owing to wet weather, had made rather poor growth, and so was only about 15 inches high at date of turning in the pigs. For some time after their introduction they failed to eat much of the crop, especially the younger lot. Very little grain was given, however, and finally both lots fed heartily upon the juicy young plants. The growing rape was pretty well eaten down by October 1, and from that date till November 30, an allowance of 4 pounds of rape per pig was fed daily from another field. The five remaining after November 30, received as much mangolds as they would eat, about 4 pounds each, daily.

The following table gives the particulars as to increase and the daily rate of gain:—

Lot No. 1.	First Weight.	Last Weight.	Gain.	Days Fed.	Daily Rate of Gain.	Remarks.
No 81	59	176	117	119	·97	Pure bred Chester White.

[illegible]	30	45	15	... .	....	Died September 6.
Total.	216	923	717	148	* ·95	

* Average rate of gain.

One pig in lot No. 2 died after being fed for thirty-five days. The pigs in lot No. 2 appeared to be too young to introduce upon rape, as they did not thrive for about a month after being confined in the lot. The dew and moisture from the plants seemed to affect them, causing their skin to crack. Lot No. 1 was not affected in this way.

Below is a statement of cost and proceeds of eleven finished hogs :—

Eleven pigs at $2, average	$22 00
Rent of lot	2 00
3,000 pounds rape and roots at $2 per ton	3 00
4,402 pounds meal at $1 per cwt	44 02
	$71 02
Proceeds of 1,988 pounds of pork at $4.50 per cwt	$89 46
Net profit	18 44

It was, of course, impossible to determine the quantity of rape grown on the lot, so a rental of $2 is charged for the one-quarter acre.

Below is a statement of the results and criticisms at the Geo. Matthews Co. packing house, Hull, Que. :—

Pig No.	Live Weight.	Dressed Weight.	Per cent Dressed.	Date of Killing.	Yard Criticism.	Quality of Pork.
81	176	128	72·7	Nov. 30....	Straight..	Poor.
82	190	136	71·6	" 30....	"	Fair.
83	180	133	73·9	" 30 ...	"	Very poor.
84	190	136	71·6	" 30....	"	"
85	191	144	75·4	" 30....	"	Fair.
90	173	125	72·2	" 30....	Short......	Poor.
86	165	125	75·7	Dec. 29 ..	Straight......	Good.
87	190	137	72·1	" 29....	"	Very good.
88	161	118	73·3	" 29....	"	"
89	170	121	71·2	" 29....	"	"
91	202	147	72·7	" 29....	"	Good.

The date of killing is given in each case, since, though all were treated in the same way till November 30, after that date the remaining pigs were fed roots instead of rape. It will be observed that the lot killed December 29, were all firm in quality, any one of them being superior to the best in Lot No. 1, killed November 30.

COST OF PRODUCING PORK.

The two lots produced in all 1,434 pounds of pork during the period of the experiment. The cost of feed was $49.02, thus making the cost of 100 pounds increase $3.42. This being very materially less than the average cost of producing pork on gain alone is thus of considerable interest. Had the pigs been from earlier litters a still lower cost per pound increase would doubtless have been the result, since the cold weather necessitated a larger grain ration.

THE DAIRY.

It is aimed to make the dairy in connection with the dairy herd such as might be of use as a model for any farmer desirous of carrying on a private dairy enterprise. A new turbine separator was put in this year and is giving satisfaction. The other appliances are older, but are suited to the work in hand. The refrigerator chamber has been recently remodelled upon the most approved and scientific plans.

The work carried on is the testing of home dairy appliances to a limited extent, the testing of samples of milk, cream, etc., sent in from time to time, and the carrying on of experimental work in pasteurizing, ripening and churning cream. All this is subordinate, however, to the manufacturing of the farm milk produce into butter. During the year 135,346 pounds of milk was handled.

THE FARM.

It was decided in the early part of the year that some 200 acres of land be set apart to be managed, so far as our peculiar circumstances will permit, just as any other farm of similar proportions might be managed. Below will be found a report of the treatment, and of the crops upon this 200 acres.

SOIL.

The land included in this area has been, heretofore, under no regular rotation of crops and is of a varied character indeed. No particular kind of soil may be said to constitute the principal part of the area. Some of the varieties well represented are, blue clay, white clay, loamy clay, clayey loam, loam, sandy loam, loamy sand, red sand, white sand, gravel and muck. Much of the sub-soil is a clayey hard-pan, lying from 1 to 30 inches below the surface.

ROTATION.

The whole 200 acres has been divided into five lots of about 40 acres each. These will in turn be under similar crops, thus making up a regular rotation of five years duration. The first year might be said to be pasture; the second, pease, and oats and pease mixed, seeded with clover; the third, corn, potatoes and roots; the fourth, cereal crops of oats, barley and wheat and seeded down with Timothy and clover; the fifth, meadow.

Below is a diagrammatic representation of the rotation with the successive crops indicated on the different plots.

1899—Pasture. 1900—Pease, mixed crop seeded to clover. 1901—Corn, roots, &c. 1902—Cereal crop, seeded down. 1903—Hay. 1904—Pasture, &c.	1899—Hay. 1900—Pasture. 1901—Pease, mixed crops, seeded to clover. 1902—Corn, roots, &c. 1903—Cereal crop, seeded down. 1904—Hay.
1899—Pease, mixed crop, seeded to clover. 1900—Corn, roots, &c. 1901—Cereal crop, seeded down. 1902—Hay. 1903—Pasture. 1904—Pease, mixed crop, seeded to clover, &c.	1899—Corn, roots, &c. 1900—Cereal crop, seeded down. 1901—Hay. 1902—Pasture. 1903—Pease, mixed crop, seeded to clover. 1904—Corn, roots, &c.
1899—Cereal crop, seeded down. 1900—Hay. 1901—Pasture. 1902—Pease, mixed crop seeded to clover. 1903—Corn, roots, &c. 1904—Cereal crop, seeded down, &c.	

CULTIVATION.

The sod or pasture land is ploughed in July and August, a shallow furrow of not over 4 inches being turned. Depending upon the weather, this is at once rolled or

disc-harrowed. During the remainder of the summer it is cultivated at intervals with the broad share cultivator, to destroy weeds and aid in the decomposition of the sod.

The succeeding spring it is cultivated and sown to pease, and mixed crop with clover.

Immediately after harvest, it is gang ploughed and kept free of weeds till late autumn by use of harrow and cultivator.

Corn, potatoes, and roots follow the next spring, the land having been manured the preceding autumn or during the winter.

Previous to sowing the corn, potatoes and roots in the spring, the subsoil is stirred by means of a deep cutting cultivator, which loosens the soil to a depth of about 8 inches.

After the harvesting of the corn, potatoes, &c., the land is put in narrow drills instead of being ploughed. In the case of corn land, the drills are about 21 inches apart, and thus contain the rows of corn and roots in alternate drills. This may be done most rapidly by using the double mould board plough.

The drills are broken down the next spring, by the disc harrow or spring tooth cultivator and the land put under oats, barley and wheat, and seeded down with a mixture of Red clover, Alsike clover, and Timothy.

After the crop of hay has been cut the succeeding summer, the cattle are turned upon it.

Shallow ploughing will, as is quite evident, retain the humus near the surface of the soil, so rendering it easily and quickly available to the young plants, as well as keeping it where it will best serve the most useful ends, of conserving soil moisture and improving the physical conditions of the soil. The use of the deep cutting cultivator will loosen the upper subsoil, and allow any surplus water to sink and the deeper growing roots to penetrate at will.

DRAINING.

Much of the 200 acre section is low lying land, with very poor natural drainage either by flow or percolation. It has been decided to supplement these and the already existing tile drains by a complete system of underground drains. With this end in view, a large main drain, 12 inches in diameter, was put down the past autumn and some progress made in the laying of the lesser mains and laterals. This work will, it is expected, be continued until all the low parts have been properly drained.

MEADOWS.

Owing to insufficient drainage, a large proportion of the clover was winter-killed, thus rendering our hay crop rather light. The quality was excellent, however, and we succeeded, in spite of adverse weather conditions, in saving it in good condition.

THE PASTURE.

One lot of 40 acres, as indicated in the diagram, was used for pasture during the past season. This section had been down to hay for 2 years, and so did not afford very good feed for our dairy stock. To this disadvantage was added the unfavourable character of the season, the large rain-fall in July rendering about one-quarter of the whole section valueless.

THE GRAIN CROPS.

Wheat: Only three varieties were grown this year. Detailed reports are as follows:

Preston.—1 acre. The soil was a heavy sandy loam, partly clay, of good quality, manured in the autumn of 1894 with about 18 tons of barn-yard manure per

acre. No fertilizer had been applied subsequently. The previous crop was sunflowers and English Horse beans. It was ploughed in the autumn of 1898 about 8 inches deep, and the following spring it was disc-harrowed once, and harrowed twice with the smoothing harrow before sowing. Sown April 29, 1½ bushels per acre; came up May 7, and was ripe August 3. The time to mature was 96 days. Yield per acre, 24 bushels 31 pounds; weight per bushel, 60½ pounds. Length of head, 3¼ to 3½ inches; bearded; length of straw, 40 to 46 inches. Growth, medium to strong; all standing well. There was no smut, but a small amount of rust.

Percy.—1 acre. This and the next plot were adjoining Preston. The soil was similar, and so were the preparation and treatment of the land. Sown, April 29, 1½ bushels per acre; came up May 7, and was ripe August 7. The time to mature was 100 days. Yield per acre, 21 bushels; weight per bushel, 57¾ pounds; length of head, 3 to 3½ inches; beardless; length of straw, 38 to 44 inches. Growth medium to strong; all standing well. There was no smut, and very little rust.

Stanley.—2 acres. Sown April 29, 1½ bushels per acre; came up May 7, was ripe August 7. The time to mature was 100 days. Yield per acre, 20 bushels 40 pounds, weight per bushel, 60½ pounds. Length of head, 3 to 3¼ inches; beardless; length of straw, 40 to 42 inches. Growth, medium and even; all standing well. There was no smut, and very little rust.

MIXED CROPS.

Mixture composed of oats 1½ bushels, pease ¾ bushel per acre. Mixed crop, 6¼ acres. Soil, a sandy loam of fair quality, a part of it peaty. The previous crop was oats. The land received an application of barn-yard manure of about 10 tons per acre in the spring of 1898. Ploughed in the autumn of 1898 about 8 inches deep, and disc-harrowed once the following spring, and harrowed twice with the smoothing harrow before sowing. Sown May 12, 2¼ bushels per acre; came up May 24, and was ripe August 15. The time to mature was 95 days. Yield per acre, 33 bushels 22 pounds. Heads large; straw very heavy, but very badly rusted. Grain very light.

FIELD CROPS OF OATS.

The following are detailed reports of the different varieties of oats grown upon the 200 acre farm:—

Fifteen sorts were grown as field crops, covering 46¾ acres in all The soil of these fields varied much in quality, which has materially affected the relative yields per acre.

Golden Giant.—3½ acres. The soil was a sandy loam of fair quality. The previous crop was corn. The land was manured in the spring of 1898 with about 12 tons of barn-yard manure per acre. It was ploughed late in the autumn of 1898 about 8 inches deep, and the following spring it was disc harrowed once and harrowed twice with the smoothing harrow before sowing.

Sown April 26, 2 bushels per acre; came up May 4, and was ripe August 14. The time to mature was 110 days. Yield per acre, 50 bushels 3 pounds, weight per bushel, 37 pounds; length of head, 9 to 11 inches sided; length of straw, 48 to 52 inches. Made a strong and even growth; standing fairly well. There was no smut, the leaves and stems were badly rusted.

Banner.—3½ acres. This variety was sown adjoining the Golden Giant; the quality of the soil and the preparation and treatment of the land was the same. Sown, April 28, 2 bushels per acre; came up May 7; ripe, August 2. The time to mature was 96 days. Yield per acre, 61 bushels 12 pounds; weight per bushel, 35¾ pounds; length of head, 9 to 11 inches, branching; length of straw, 48 to 54 inches. Growth,

strong and even; standing fairly well. There was no smut, but the leaves and stems were badly rusted.

Improved Ligowo :—6½ acres. This also was adjoining the Golden Giant, and the character and treatment of the land was similar. Sown April 28, 2 bushels per acre; came up May 7, and was ripe August 1. The time to mature was 95 days. Yield per acre, 55 bushels 3 pounds; weight per bushel, 35¾ pounds; length of head, 8 to 10 inches, branching; length of straw, 48 to 54 inches. Made a strong and even growth; was considerably lodged, although straw fairly strong. There was no smut, but the leaves and stems were badly rusted.

Golden Beauty.—Soil, a sandy loam of fair quality, with patches of heavier soil, which were partly clay. This land received a dressing of about 15 tons of barn-yard manure per acre in the spring of 1897. No fertilizer had been applied subsequently, but a heavy sod had been ploughed under in the spring of 1899. This plot had been sown with permanent pasture mixture in the spring of 1898, with barley as a cover crop. The land was ploughed in the spring and disc harrowed once, and harrowed twice with the smoothing harrow before sowing. Sown May 5, 2 bushels per acre; came up, May 12, and was ripe August 3. The time to mature was 90 days. Yield per acre 57 bushels 3 pounds; weight per bushel, 35½ pounds; length of head, 7 to 10 inches, branching; length of straw, 48 to 54 inches; made a strong, even growth, standing fairly well; few spots lodged. There was no smut, but the leaves and stems were slightly rusted.

American Beauty.—5 acres. This was adjoining the 3½ acres of Golden Beauty, and the character and treatment of the land were similar. Sown May 5, 2 bushels per acre; came up May 12, and was ripe August 3. The time to mature was 90 days. The yield per acre was 45 bushels 25 pounds; weight per bushel, 34 pounds; length of head, 8 to 10 inches; branching; length of straw, 48 to 52 inches. Growth strong and even. Standing fairly well, few spots lodged. There was no smut, but the leaves and straw were considerably rusted.

Bavarian.—4 acres. The soil was a sandy loam of fair quality, which was manured in the spring of 1896 with about 10 tons of barn-yard manure per acre. The previous crop was 2 acres clover, 1 acre Brome grass, 1 acre permanent pasture mixture. This was not ploughed in the autumn, but was ploughed about 4 inches deep in the spring of 1899, and disc harrowed once and harrowed three times with the smoothing harrow before sowing. Sown May 6, 2 bushels per acre; came up May 12, and was ripe August 8. The time to mature was 94 days. Yield per acre, 40 bushels 19 pounds; weight per bushel, 30 pounds; length of head, 9 to 10 inches; branching; length of straw 48 to 50 inches. Part of plot made a strong, even growth, some was considerably lodged. There was no smut, but leaves and stems were badly rusted.

Wallis.—3½ acres. The soil was a sandy loam of fair quality, which was manured in the spring of 1896 with about 10 tons of barnyard manure per acre. The previous crop was clover. This was not ploughed in the autumn, but was ploughed about 4 inches deep in the spring of 1899, and disc harrowed once, and harrowed three times with the smoothing harrow before sowing. Sown May 6, 2 bushels per acre; came up May 12, and was ripe August 8. The time to mature was 94 days. Yield per acre, 41 bushels 29 pounds; weight per bushel, 30 pounds; length of head, 9 to 11 inches, branching; length of straw, 48 to 50 inches. Growth, strong and even, and was considerably lodged. There was no smut, but the leaves and stems were considerably rusted.

Abundance.—3 acres. Soil, part clay loam, part sandy loam, and part peaty. This land was manured in the spring of 1896 with about 12 tons of barn-yard manure per acre. Half of field in autumn 1898, and balance in spring of 1899, thick mats of clover were ploughed under. The previous crop was barley, with which the clover was sown

at the rate of 10 pounds of seed per acre. Half of each plot was ploughed in the autumn of 1898, balance of field was ploughed in the spring of 1899, disc harrowed once, and harrowed twice with the smoothing harrow before sowing. Sown May 6, 2 bushels per acre, came up May 13, and was ripe August 8. The time to mature was 94 days. Yield per acre, 41 bushels 31 pounds; weight per bushel, 34½ pounds; length of head, 8 to 9 inches, branching; length of straw, 40 to 42 inches; growth, strong and even, and was considerably lodged. There was no smut, but the leaves and stems were slightly rusted.

Salines.—1 acre. This and the five following plots were adjoining that of Abundance. The soil was similar, and the preparation and treatment of the land the same. Sown, May 6, 2 bushels per acre; came up May 13, and was ripe August 14. The time to mature was 100 days; yield per acre, 27 bushels 17 pounds; weight per bushel 25½ pounds; length of head, 9 to 11 inches branching; length of straw, 40 to 46 inches. Growth, strong and even, and all standing well. There was no smut, but the leaves and stems were badly rusted.

Columbus.—1 acre. Sown, May 6, 2 bushels per acre; came up, May 14, and was ripe August 11. The time to mature was 99 days. Yield per acre, 35 bushels 15 pounds; weight per bushel, 32 pounds; length of head, 8 to 10 inches, branching; length of straw, 40 to 46 inches. Made a medium growth, straw considerably broken down. There was some smut, and the leaves and stems were slightly rusted.

Black Tartarian.—1 acre. Sown, May 6, 2 bushels per acre; came up, May 13, and was ripe August 12. The time to mature was 98 days. Yield per acre, 23 bushels 3 pounds; weight per bushel, 23 pounds; length of head, 9 to 11 inches, branching; length of straw, 46 to 54 inches. Growth, strong and even, and all standing well. There was no smut, but the leaves and stems were very badly rusted.

California Prolific, Black.—1 acre. Sown, May 6, 2 bushels per acre; came up, May 13, and was ripe August 12 The time to mature was 98 days. Yield per acre, 20 bushels 30 pounds; weight per bushel, 23 pounds, length of head, 9 to 11 inches, branching; length of straw, 46 to 52 inches. Growth strong and even, all standing well. There was no smut, but the leaves and stems were badly rusted.

Joanette.—2 acres. Sown, May 6, 1¾ bushels per acre; came up, May 13, and was ripe August 14. The time to mature was 100 days. Yield per acre, 42 bushels 17 pounds, weight per bushel 29¾ pounds; length of head, 7 to 9 inches, branching; length of straw, 33 to 40 inches. Growth, strong and even, and all standing well. There was no smut, but the leaves and stems were badly rusted.

Siberian.—4 acres cut green. Sown, May 7, 2 bushels per acre; came up, May 13, and was ripe August 11. The time to mature was 97 days. The yield per acre was 42 bushels; weight per bushel, 36 pounds; length of head, 9 to 10 inches, branching; length of straw, 44 to 50 inches. Made a strong, even growth, all standing well. There was no smut, but the leaves and stems were slightly rusted.

White Schonen.—3 acres. Soil a sandy loam of fair quality. The previous crop was oats. The land received an application of barn-yard manure of about 10 tons per acre in the spring of 1898. The land was ploughed in the autumn of 1898 about 8 inches deep, and disc-harrowed once the following spring, and harrowed twice with the smoothing harrow before sowing. Sown, May 12, 1¾ bushels per acre, came up, May 20, and was ripe August 14. The time to mature was 93 days. The yield per acre was 32 bushels 5 pounds; weight per bushel 24½ pounds; length of head, 8 to 10 inches, branching; length of straw, 44 to 50 inches. Made a strong, even growth; all standing well. There was no smut, but the leaves and stems were considerably rusted.

FIELD CROPS OF BARLEY.

Six varieties of barley were grown, occupying $11\frac{1}{2}$ acres in all. Below is a detailed report of the same :

Canadian Thorpe.—2 rowed, 1 acre. Soil a sandy loam, rather light, of poor quality ; received a coating of barn-yard manure of about 12 tons per acre in the spring of 1895. No manure or other fertilizer has been applied since, except two good crops of green clover, which had been sown with previous crops. The previous crop was oats. The land was ploughed in the spring about 4 inches deep, when a good mat of clover was turned, under and harrowed 8 times with the smoothing harrow before sowing. Sown, May 10, 2 bushels per acre ; came up, May 21, and was ripe August 8. The time to mature was 89 days. Yield per acre, 28 bushels 21 pounds : weight per bushel, $52\frac{1}{4}$ pounds ; length of head, 3 to $3\frac{1}{2}$ inches ; length of straw, 36 to 42 inches. Growth, strong and even ; all standing well. There was no smut, but the leaves and stems were slightly rusted.

Sidney.—2 rowed, 1 acre. This and the four following plots were adjoining that of Canadian Thorpe. The soil was similar and the preparation and treatment of the land the same. Sown' May 10, 2 bushels per acre ; came up May 21, and was ripe August 7. The time to mature was 88 days. Yield per acre, 32 bushels 14 pounds ; weight per bushel, 51 pounds ; length of head, $3\frac{1}{2}$ to 4 inches ; length of straw, 36 to 42 inches. Growth strong and even ; standing fairly well. There was no smut ; leaves and stems were slightly rusted.

Champion.—1 acre. Sown, May 10, $1\frac{3}{4}$ bushels per acre ; came up, May 21, and was ripe August 6 The time to mature was 87 days. Yield per acre, 23 bushels 11 pounds, weight per bushel, $43\frac{1}{4}$ pounds ; length of head, 3 to $3\frac{1}{4}$ inches, beardless ; length of straw, 36 to 42 inches. Growth, medium to weak ; all standing well. There was no smut, but the leaves and stems were slightly rusted.

Trooper.—6 rowed 1 acre. Sown, May 10, $1\frac{3}{4}$ bushels per acre ; came up, May 21, and was ripe August 8. The time to mature was 89 days. Yield per acre, 24 bushels 25 pounds ; weight per bushel, $52\frac{1}{2}$ pounds ; length of head, $2\frac{3}{4}$ to 3 inches ; length of straw, 30 to 36 inches. Growth uneven, weak ; all standing. There was no smut, but the leaves were slightly rusted.

Royal.—6 rowed, 1 acre. Sown, May 10, $1\frac{3}{4}$ bushels per acre ; came up, May 21, and was ripe August 7. The time to mature was 88 days. Yield per acre, 24 bushels 5 pounds ; weight per bushel, 51 pounds ; length of head, 3 to $3\frac{1}{4}$ inches ; length of straw, 36 to 42 inches. Growth even, medium to weak ; all standing well. There was some smut, and leaves and stems were slightly rusted.

Mensury.—$6\frac{1}{2}$ acres. Sown, May 10, $1\frac{3}{4}$ bushels per acre ; came up, May 21, and was ripe August 7. The time to mature was 88 days. Yield per acre, 40 bushels 11 pounds ; weight per bushel, $52\frac{1}{4}$ pounds ; length of head, $3\frac{1}{4}$ to $3\frac{1}{2}$ inches ; length of straw, 42 to 44 inches. Growth strong and even ; all standing well. There was no smut, but leaves and stems were slightly rusted.

FIELD CROPS OF PEASE.

A number of varieties of this legume were sown, but immediately after cutting, and before ready to store, a very strong wind storm arose, which mixed the varieties so much as to render it impossible to distinguish one kind from another. The following is, therefore, a general report upon the field :

Pease.—$15\frac{1}{2}$ acres. Soil, part sandy loam of rather poor quality, and part peaty. Six acres of the land manured in the autumn of 1898 with about 12 tons of barn-yard

manure per acre: balance of field manured in the spring of 1897 with about 12 tons of barn-yard manure per acre. It was all ploughed in the autumn of 1898 about 8 inches deep, and the following spring it was disc harrowed once, and harrowed twice with the smoothing harrow before sowing. The previous crop was part hay; balance, oats. Sown, May 10, 2½ bushels per acre; came up May 23, and was ripe August 15. The time to mature was 96 days. Yield per acre, 18 bushels 32 pounds: weight per bushel 62¼ pounds. This field suffered from water several times during the summer, the yield per acre being for this reason considerably less than would have been the case under better conditions.

ENSILAGE CORN.

About 17 acres was under corn for ensilage. The following three varieties were sown adjoining each other on similar soil, and received similar treatment. The soil was a heavy sandy loam of good quality, more or less mixed with clay. The previous crop was clover. The land was ploughed late in the autumn of 1898, when a good swarth of second growth clover was ploughed under. The land received an application of barn-yard manure of about 15 tons per acre, which was distributed on the frozen ground in small piles of about one-third of a cart-load each, and spread in the spring. It was then ploughed under about 4 inches deep and harrowed with the smoothing harrow before sowing.

Longfellow.—7 acres. Sown, May 25, in rows 35 inches apart: came up, June 7, and was cut for ensilage September 13. Growth, medium to weak, on account of water, leafy from top to bottom, and 5 to 8 feet high; the stalks were poorly eared; ears beginning to glaze. Yield per acre, 10 tons 75 pounds.

Angel of Midnight.—2 acres. Sown, May 25, came up June 7, and was cut for ensilage September 15. Growth, uneven, weak, on account of wet weather; leafy from top to bottom, and from 4 to 7½ feet high; stalks were poorly eared; ears in dough state. Yield per acre, 8 tons 12½ pounds.

Compton's Early.—2 acres. Sown, May 25; came up, June 7, and was cut for ensilage September 15. Growth, uneven, weak; leafy from top to bottom; height, 4 to 7⅓ feet; stalks, fairly well eared; ears in dough state. Yield 11 tons 1,555 pounds per acre.

Selected Leaming.—2 acres. Soil part sandy loam and part peaty. The previous crop was oats. The land received an application of barn-yard manure of about 15 tons per acre, which was distributed on the frozen ground in small piles of about ⅓ of a cart load each, and spread in the spring. It was then ploughed under about 4 inches deep, and harrowed twice with the smoothing harrow before sowing. Sown, May 25; came up, June 7, and was cut for ensilage September 16. Growth, strong and even; leafy at top and very few leaves at bottom; height, 8 to 11 feet; stalks eared well; ears in late milk or early dough. Yield per acre, 11 tons 1,340 pounds.

Cloud's Early Yellow.—⅓ acre. This and the next five plots referred to were adjacent to the Selected Leaming; the soil was very similar, and so were the preparation and treatment of the land. Sown, May 25; came up, June 7, and was cut for ensilage September 16. Growth, medium, leafy at top, fewer leaves at bottom; height, 8 to 10 feet; stalks, well eared; ears in dough state. Yield, 9 tons 1,619 pounds per acre.

Giant Prolific Ensilage Sweet.—½ acre. Sown, May 25; came up, June 7, and was cut for ensilage September 18. Growth, strong, even, leafy at top with very few leaves at bottom; height, 10 to 11 feet, ears fairly plentiful in late milk stage. Yield, 11 tons 190 pounds per acre.

White Cap Yellow Dent.—½ acre. Sown, May 28; came up, June 7, and was cut for ensilage September 18. Growth uneven on account of water. Leafy top to bottom; height, 9 to 11 feet; stalks fairly well eared; ears in late milk. Yield, 13 tons 30 pounds per acre.

Mammoth Cuban.—½ acre. Sown, May 35; came up, June 7, and was cut for ensilage September 18. Growth strong and even, leafy on top, fairly leafy on bottom; height, 10 to 12 feet; stalks well eared, ears in late milk. Yield per acre, 13 tons 1,880 pounds.

Early Mastodon.—½ acre. Sown, May 25; came up, June 7, and was cut for ensilage September 18. Growth strong and even; leafy on top, fairly leafy on bottom; height, 10 to 12 feet; stalks well eared, ears in dough stage. Yield per acre, 14 tons 110 pounds.

Eureka.—½ acre. This and the two following plots were adjoining each other. The soil was similar and so were the preparation and treatment of the land throughout. Soil sandy loam, good quality. The land was manured in 1896 about 12 tons per acre.

Eureka: Sown, May 26; came up June 1, and was cut for ensilage September 19. Growth, strong, leafy on top, almost clean at bottom; no ears; height, 10 to 11 feet. Yield per acre, 14 tons 1730 pounds.

Iowa Silver Mine.—½ acre. Sown, May 26; came up, June 1, cut for ensilage September 19. Growth, strong, leafy on top, very few at bottom, no ears; height 10 to 11 feet. Yield per acre, 13 tons 820 pounds.

Iowa Gold Mine.—½ acre. Sown, May 26; came up June and was cut for ensilage September 19. Growth strong and even, leafy on top, very few at bottom; height, 10 to 12 feet, no cobs or ears. Yield per acre, 14 tons 1380 pounds.

FIELD PLOTS OF MANGELS.

The following seven plots were all sown in the same field adjoining each other, on similar soil and with similar treatment. The soil was a sandy loam of fair quality, and the previous crop was roots. The land was ploughed in the autumn of 1898, about 8 inches deep, and in the spring of 1899 it was grubbed about 6 inches deep, and harrowed with the smoothing harrow. The land was then made up in drills 2 feet apart and subsequently rolled with a heavy land roller which flattened the ridges nearly one-half, leaving a firm seed bed. The seed was then sown at the rate of 3 pounds per acre. All sown May 8, came up May 17; pulled, October 17.

	Yield per acre. Tons.	Lbs.	Yield per acre. Bush.	Lbs.
Gate Post 2 acres	11	1,950	399	10

Purple Top Swede.—Soil a sandy loam of fair quality. This land received a dressing of about 12 tons of barn-yard manure per acre, distributed fresh from the barn-yard in small piles of about one-third of a cart load each during the winter, was spread in the spring, and ploughed under in spring of 1899 about 4 inches deep, and harrowed twice with the smoothing harrow. The land was then made up in drills two feet apart and subsequently rolled with a heavy land roller which flattened the drills nearly one-half, leaving a firm seed bed. The seed was sown at the rate of 2 pounds per acre. Sown, June 7; came up June 13, pulled November 6.

FIELD CROPS OF POTATOES.

The following table gives particulars of the results obtained from fifteen plots which were all grown adjoining each other in the same field. The land was similar throughout, and the preparation and treatment was the same for all. The soil was a light sandy loam, and the previous crop was barley. This land received an application of fresh barn-yard manure of about 12 tons per acre in spring of 1899, it was ploughed under 4 to 5 inches deep, harrowed with the smoothing harrow. The land was then made up in drills $2\frac{1}{2}$ feet apart, and 6 inches deep for planting.

SORGHUM.

The value of sorghum as a fodder crop is in some sections very great. It needs a rather dry warm spring, however, and is, therefore an uncertain crop in this latitude. The cultivation required is quite similar to that demanded by corn.

Two varieties were sown this year, Early Amber and Early Orange.

One-half acre Early Amber was sown 8 pounds to the acre, June 1. A period of cold wet weather followed and for six weeks it made very little progress. In August the dry hot weather suited it well and it made great growth. It was fed green to swine and was eaten with great relish by these animals.

One half acre Early Orange was sown 8 pounds to the acre, May 25. It failed to germinate, however, and had to be sown over again on June 12. This variety was thus even more backward than the Early Amber. It was fed green to swine.

RAPE.

The value of this plant as a soiling crop can scarcely be overestimated. It is very little cultivated by our farmers, however, too many of whom appear to know nothing of its great value.

It yields a large crop of very succulent and nutritious forage valuable as pasturage for sheep or swine and may be fed to cattle with good results. The method of cultivation is similar to that required for turnips, save that the plants do not need to be thinned in the row.

It will yield two crops in the season of from 3 to 6 tons per acre each if cut, and if pastured will stand very heavy stocking. Dwarf Essex is the variety best suited for common use and should be sown at the rate of about 3 pounds per acre.

It may be sown broadcast as well as in drills, when almost equally good results are obtained but if the soil is weedy it will be found advantageous to sow in drills. The soil for this crop needs to be well manured.

The date of sowing may be varied and a good crop may be anticipated from seed sown any where from May 10, to Aug. 15. It is thus possible to grow a crop of rape upon a grain field after harvest in the same year.

About $1\frac{1}{4}$ acres was sown to rape alone the past season, most of this was fed to swine, some of it to sheep, and pigs were pastured upon a small lot with very good results. On an acre of land sown to oats about 5 pounds of rape seed was drilled in from the grass seed box of the seeder at the same time as the oats were sown (May 4.) This lot did not succeed very well and appeared to have been sown too thinly. It yielded between 2 and 3 tons per acre in September.

REPORT OF THE HORTICULTURIST.

(W. T. Macoun.)

Dr. Wm. Saunders,
Director Dominion Experimental Farms,
Ottawa.

Sir,—I have the honour to submit, herewith, for your approval, the thirteenth annual report of this division. Owing to the large number of branches of horticultural work included in this division, it is not possible in the annual report to give in detail all the experiments conducted and the results obtained during the year, but the matter contained in the following pages is that which was thought to be of greatest value and interest to farmers and fruit growers throughout Canada.

CHARACTER OF SEASON.

The winter of 1898-9 was one of the most disastrous in the history of fruit growing in southern and south-western Ontario; thousands of peach trees were root-killed, and other fruits suffered badly, the results being that the bright prospects of many a fruit grower were dashed to the ground. In northern and eastern Ontario this was not the case, what winter-killing there was being about normal. Very little snow fell at Ottawa during the early part of last winter, and it was feared at one time that winter-killing would be severe, but during the month of March more than 44 inches of snow fell. This came at a very opportune time, preventing the thawing and freezing of the ground, which is liable to take place during March and early in April, and which often proves very harmful to fruits. It was not an early spring this year, though not a very late one. The frost was out of the ground enough to use the spade on April 18, which was six days later than last year. The weather was comparatively cool during April and May. Little rain fell during April and the early part of May, but from the latter part of that month until the end of July there was rain in plenty. In July, alone, 9·85 inches fell. It was not a warm summer and crops which require much heat did not do as well as usual. Beginning with August 1, there was little rain until September 11, but in the horticultural department the lawn grass was all that suffered very much. Copious rain fell during September, October and November. On September 23, a frost killed the tomatoes, cucumbers, melons, squash and other tender things, but on October 2 there was one much more severe, which froze the ground to a depth of about three-fourths of an inch. This frost killed the leaves on the grape vines, and injured the fruit very much. October and November were exceptionally mild months and outside work was continued up to December 2. Winter set in on December 4, eight days later than last year.

FRUIT CROP.

There was a light crop of apples this year, what fruit there was being of good quality, however. There were a few pears on some of the trees, but all were of inferior varieties. The crop of native plums was light also, though a few trees were well loaded. Cherries were a failure altogether. If the season had been favourable there would have been an excellent crop of grapes, but the weather was not hot enough at the time of ripening, the result being that many varieties failed to mature and a severe frost coming

on October 2 injured them badly. There were good crops of small fruits, strawberries doing especially well.

PROGRESS OF THE WORK.

The work in connection with this division has made satisfactory progress this year, and much useful information has been obtained and data accumulated, which will be published from time to time to help forward the interests of horticulture in this country.

In the orchards and small fruit plantations the trees and bushes have received careful attention. Records were kept of the hardiness, growth and yield of the different varieties, and descriptions taken of as many of them as possible. The trees were thoroughly sprayed, as usual, and experiments conducted with different mixtures and solutions. One experiment, which was made, in whitewashing trees to prevent the swelling of the buds, while yielding affirmative results in that respect, showed the value of whitewash in ridding trees of the oyster-shell bark-louse.

New strawberry and gooseberry plantations were made this year, in which about 350 varieties of strawberries and 124 varieties of gooseberries are being tested.

Tobacco was grown to a larger extent than usual, there being 1½ acres devoted to this crop. A curing house has been erected after the most modern plan, and with the latest system of ventilation, and good results should be had in curing tobacco in future.

The nurseries in connection with this division, which, hitherto, had been divided into two sections, some distance from each other, have been consolidated into one and a wire fence built around it, which encloses also the hot-beds.

Another large area in the Arboretum was seeded down to lawn grass, which has added very much to the appearance of the place, and will make it much easier to get about in the outlying parts.

A new permanent label of galvanized iron for trees, shrubs and plants has been adopted, which can be made cheaply and will be much more conspicuous than the smaller zinc labels hitherto used.

During the year a catalogue of the trees and shrubs growing in the Arboretum was published in conjunction with the Director, in which interesting notes are given of the species and varieties tested. The total number of species and varieties tried thus far being 3,071.

Several thousand young *Pyrus baccata* seedlings have been raised this year, which will be used for distribution to Manitoba and the North-west Territories, and for grafting and budding the hybrids, between this crab and the cultivated varieties of apples, originated by Dr. Wm. Saunders and Dr. C. E. Saunders.

The work of top-grafting the tenderer varieties of our best apples on hardy stocks has been an important feature of the work. It is hoped that some varieties that have not hitherto succeeded here will do so on these stocks.

During the past five years blossoming dates of fruits have been recorded by a large number of observers for this division. The records of the apples have been tabulated and a synopsis given in this report. It is important for the fruit grower to know the relative dates of blossoming of the different varieties, that he may plant those which bloom at the same time in close proximity. The information given in this report will help him to do this.

Through correspondence we have endeavored to render assistance to fruit growers throughout Canada. Many have expressed their appreciation of this part of the work.

MEETINGS ATTENDED AND PLACES VISITED.

It has been my privilege during the past year to attend a large number of meetings of farmers and fruit growers, and to visit some of the important Arboreta and Botanic Gardens in the United States. On January 31 and February 1, I attended the winter meeting of the Quebec Pomological Society at Montreal, and on February 21 and 22, the annual meeting of the Nova Scotia Fruit Growers' Association at Wolfville. A series

of farmers' meetings were arranged for on Prince Edward Island during the last week of February and the first week of March, during which time I addressed audiences at Rustico on February 27 ; Kensington and Summerside, on February 28 ; O'Leary and Alberton on March 1 ; St. Peters and Souris on March 2.; Charlottetown on March 3 ; Hunter River and Murray Harbour South on March 4, and Georgetown on March 6. At the invitation of the Secretary of the Ontario Fruit Growers' Association, I addressed meetings of Horticultural Societies at Brockville on March 15 ; Cardinal on March 16 ; Iroquois on March 17 ; Smith's Falls on March 21 ; Carleton Place on March 23 ; Arnprior on March 24, and Kemptville on March 28. The biennial meeting of the American Pomological Society was held at Philadelphia on September 7 and 8, at which I had the pleasure of attending. It was also my privilege to attend and to give an address at the annual meeting of the Ontario Fruit Growers' Association, which was held at Whitby on December 5 and 6. The last meeting attended was that of the Ontario Agricultural and Experimental Union, at Guelph, Ont., on December 7.

During the month of September I visited, under your instruction, the New York Botanic Garden at Bronx Park, New York, and the Arnold Arboretum, Boston, Mass., at which places much information was obtained which will be useful in our work at Ottawa. On December 8 and 9, I visited St. Catharines and Niagara and arranged for experiments in whitewashing trees to determine whether lime would destroy the San José Scale or not.

ACKNOWLEDGMENTS.

I have been greatly assisted in my work during the past year by many who have paid especial attention to certain branches of horticulture and who are authorities in their work. There are others also who have kindly furnished information on various subjects whenever asked, and who, by their willingness to assist me in matters pertaining to horticulture, have made it much easier to obtain a knowledge of some things than it otherwise would have been. To those who, for the past five years, have regularly recorded the blossoming dates of fruits for this Division I am very grateful, and fully appreciate the trouble they have taken from year to year. Their names are recorded in another part of this report. Among those who have rendered me special assistance I desire to mention Mr. W. H. Dempsey, Trenton, Ont., Prof. F. A. Waugh, Burlington, Vt., U. S., Mr. Wm. A. Taylor, Washington, D.C., U.S., Mr. R. Hamilton, Grenville, Que., Mr. G. E. Fisher, Freeman, Ont., Mr. Robert Brodie, St. Henri de Montreal.

During the year my secretary, Mr. J. F. Watson, has again shown his knowledge of the details of this Division by the accuracy he has displayed in the correspondence and in other matters relating to his work. Mr. H. Holz, foreman, has also performed his duties in a thoroughly satisfactory manner, and his assistance has been of great value to me.

DONATIONS.

The following donations were received during the year, and this opportunity is taken to gratefully acknowledge the same :—

Sender.	Donation.
Aylmer Iron Works, Aylmer, Ont	Spray pump No. 2, barrel pump.
Anderson, Wm., Woodstock, Ont	Apple scions.
Anderson, J. C., Fallbrook, Ont	Scions, Lanark Greening, Iroquois apples.
Arnold Arboretum, Boston, Mass., U.S	Collection of seeds.
Barr, Peter, London, Eng	57 species and varieties of pæonies.
Brown, C. E., Yarmouth, N.S	Scions of double-flowering hawthorn.
Craig, Wm., Maritana, Que	Scions, Guerin apple and plum trees.
Cairncross, G., London Junction, Ont	3 varieties rhubarb.
Dempsey, W. H., Trenton, Ont	Apple scions.
Foster, Mrs. S., Knowlton, Que	Scions, Hardy and Edgehill apples.
Freemantle, Henry, Coalfields, Assa	6 cuttings Freemantle Redpath Ruby Red Currant.
Hay, G. U., St. John, N.B	Specimens of American arbor vitæ and *Ilex verticillata.*
Hamilton, Robert, Grenville, Que	Apple scions.
Iowa Experiment Station, Ames, Ia., U.S	Apple scions.
Johnston, Asa. A., Cowansville, Que	Scions, Kinkead, No. 2, No. 3, No. 7, apples.
Johnstone, John, Long River, P.E.I	Sample McIntyre Potato.
Kettle, Stephen, Ursa, Ont	Seeds of gorse, broom and holly.
Lalonde, Antoine, Isle Verret, Que	Tobacco seed.
Lagace, Jules, Madawaski, Que	Scions, seedling apple.
Leef, W. H., Orillia, Ont	Scions of seedling plum.
Marsh, J. D., Mille Roches, Ont	Scions, No. 2, seedling apple.
Morris, Stone & Wellington, Welland, Ont	Apple scions.
Mallory, N.E., Guilds, Ont	25 plants Edgar strawberry.
New York Botanic Gardens, Bronx Park, N.Y	44 species perennials.
Ontario Agricultural College, Guelph, Ont	Collection of 13 varieties of strawberries, 6 varieties of raspberries.
Robson, T. A., Minden, Ont	Apple scions.
Royal Gardens, Kew, London, Eng	Collection of seeds.
Smith, E. D., Winona, Ont	1 tree Emerald plum.
Sivers, Max von, Roemershof, Russia	Seeds and plants.
Simpson, W., P.E.I	Clover roots.
Smallwood, A., Middleton, P.E.I	Plants of *Achillea Ptarmica.*
Sole, Thos., Sarnia, Ont	Scions of unknown apple.

Starr, R. W., Wolfville, N.S	Hardy roses, native spiræas, plum tree, Scions of Gravenstein and Red Gravenstein apples.
Trotter, Miss L. A., Owen Sound, Ont	Scions, seedling pear.
Tolmie, J., Victoria, B.C	Perennials.
Thonger, Prof. C. G. Freer, F.R.S., Colonial College, Hollesley Bay, Suffolk, Eng	Apple scions, Collection of 24 varieties.
Woodward, J. S., Lockport, N.Y., U.S	Scions, Milwaukee apple.
Wilson, Fred, Stouffville, Ont	Plum scions.

I have the honour to be, sir,

Your obedient servant,

W. T. MACOUN,

Horticulturist.

APPLES.

Most of the apple trees came through the winter of 1898-9 in good condition. The trees suffered most on a sandy hill, on which the snow did not lie very well and where even the cover crop failed to afford the required protection. Several of the trees were root killed and a few others had their roots injured considerably. The number of trees which died or were destroyed by storms during the year was fifty-five. Most of the trees made good growth during the past season, notwithstanding the fact that many of them are affected with what is known as "black heart." The gaps caused by the heavy losses from winter-killing during the winter of 1895-6 are fast being filled up by the young trees which were planted since that time, and the apple orchard, on the whole, looked well. The crop of apples was light this year; there were, however, 175 varieties which fruited, although only a few of the trees were well loaded. Insects were not very troublesome, although if the tent caterpillars had not been taken in time they would have caused much injury. The trees were given two sprayings to destroy the oyster shell bark-louse, which was first found running on May 29. The trees were sprayed on June 1, with tobacco water and whale oil soap, made by using 10 pounds tobacco and 2 pounds whale oil soap to 40 gallons of water. On June 6, the trees were sprayed a second time with whale oil soap at the rate of 8 pounds to 40 gallons of water. This destroyed many of the insects.

The regular sprayings were made with sulphate of copper and Bordeaux mixture; once with sulphate of copper and four times with Bordeaux mixture. There was practically no scab on the fruit this season, and the codling moth did not affect it so much as last year. The dry rot, of which mention is made elsewhere, affected a number of varieties but did not appear any worse than last year.

DESCRIPTION OF VARIETIES.

A few varieties of apples not hitherto described in the reports of the horticulturist are worthy of special mention this year.

Shiawassee Beauty.—Medium size, oblate or flat, regular; skin yellow, washed over nearly the whole surface with deep red; dots few, pale, distinct, but not prominent; cavity, medium depth, open; stem, medium length, slender; basin, medium depth and width, smooth; calyx partly open. Flesh white, crisp, very tender, juicy, mild subacid, pleasant flavour, core small; skin thick and tough. Quality very good. Season, November, December. Tree a medium, spreading grower, fruiting heavily every other year. Originated in Michigan.

Milwaukee—Large, oblate; skin pale yellow, well splashed and washed with bright red and crimson; dots moderately numerous, small, white, distinct; cavity, deep, medium width, slightly russetted; stem short, slender; basin deep, open, slightly wrinkled; calyx, large, open. Flesh yellowish, crisp, tender, melting, juicy, acid; core medium size; skin moderately thick and moderately tough. Quality above medium, almost good. Season December to February. A handsome apple, excellent for cooking. A tree planted in 1895 bore heavily this year. It is a seedling of Duchess originating with Mr. Geo. Jeffery, Milwaukee, Wisconsin.

Walter—Very large, roundish, rather irregularly ribbed; skin pale yellowish green streaked and splashed with red, heavier on sunny side; dots few, small, white, distinct; cavity deep, medium width; stem short; moderately stout; basin deep and medium width; calyx closed. Flesh yellow, tender, melting, juicy, brisk subacid; core small, skin moderately thick, fairly tender. Quality above medium, almost good. Season October. Tree an upright moderate grower, bearing heavily every other year. Originated by the late P. C. Dempsey, Trenton, Ont. A cross between Northern Spy and Golden Russet, the former being the female parent. The original tree fruited for the first time in 1891. A very handsome apple.

Lawver (Delaware Red Winter).—Above medium size, roundish, broadly ribbed. Skin yellow, nearly all or all, washed with bright red; dots few, pale, distinct; cavity medium in depth, narrow; stem long, slender; basin very shallow, narrow, wrinkled; calyx closed. Flesh yellow, sometimes faintly tinged with pink, tender, crisp, juicy, sprightly subacid, aromatic; core small; skin thick and tough. Quality above medium. Season, January to June, but will keep for more than a year. An annual, but a shy bearer at the Experimental Farm. Tree a medium, spreading grower. In 1898 there was so marked a difference between the fruit of the Lawver and the apple we have under the name of Delaware Red Winter, that they were thought to be quite distinct, but this year no difference can be detected. The description made of the Delaware Red Winter last year differed from the one given above in these particulars:—Brighter in colour than Lawver; cavity a little broader, basin deeper, calyx larger; flesh not tender as in Lawver; sub-acid, not sprightly; skin tenderer than Lawver. Why this difference should have occurred is still a mystery. The difference was not confined to a few specimens, all being the same. The fruit was picked about the same time. Others who saw the two apples in 1898 thought them distinct varieties. We are now quite confident that Delaware Red Winter is a synonym of Lawver.

RUSSIAN APPLES.

There were not so many of the Russian varieties of apples fruited this year as last, but those that did were carefully compared in order to continue the work of eliminating synonyms; descriptions were made of most of the kinds which ripened, and notes taken on the growth of the trees. Each year adds convincing proof of how little value most of these varieties are in all but the extreme limits of successful apple culture. While a large number of the trees are suffering from 'black heart,' which has affected them for several years, many of those which were badly affected with blight in 1893, and were severly pruned in consequence, are regaining symmetrical proportions. Last winter and during the past summer 23 trees died or were blown down; all of which were rotten at the root.

The following are the varieties which have this year been found fruiting under different names, or found to be different varieties under the same name. As we are not yet sure of the proper names for these varieties, it is impossible to say which are the synonyms:—

Green Sweet. Lebonkey Sweet. Described, August 8. Fruit large, roundish, sometimes oblate; skin pale yellow, a considerable number of pale yellow dots; cavity medium in depth, narrow, stem short, stout; basin medium depth and width, considerably wrinkled. Flesh white, firm, moderately juicy, acid, astringent; core small, skin moderately thick, tender. Poor quality. Not promising.

Herrin. Osimoe 7 M., 57 M., Good Peasant, Beautiful Arcade. Described August 19. Fruit large, roundish, pale-green, with a purplish pink blush on sunny side, dots few, white, obscure; cavity medium in depth, narrow, stem short, moderately stout; basin medium depth and width, slightly to considerably wrinkled, calyx open. Flesh white, juicy, sweet, fair flavour, core small, skin thick and tough. Medium quality. A pleasant flavoured sweet apple.

Antonovka. Cinnamon, German Calville, Yellow Arcade. Described October 5. Fruit large, irregular, oblong, roundish or slightly conical, ribbed; skin yellow, a few pale-green obscure dots which, being raised, make the skin rough to the touch; cavity deep, moderately open, russetted; stem short, stout; basin deep, narrow, slightly wrinkled; calyx closed. Flesh yellow, firm, moderately juicy, tender, brisk sub-acid, with a peculiar, pleasant, spicy flavour; core small; skin thick, tender. Quality, almost good. Season, October. Better than most of the Russian varieties.

Bogdanoff. Repka Winter, Tested December 14. Fruit above medium size, oblate, ribbed though not prominently; skin yellowish-green, well streaked and splashed with purplish red; dots few, obscure; cavity deep, of medium width, russetted; stem short, moderately stout; basin deep, medium width, slightly wrinkled; calyx open; flesh white, crisp, moderately juicy, mild sub-acid; core, small; skin, thick, rather tough. Medium quality. Season, December, January.

Grandmother. Bogdanoff, Bogdanoff Steklianka, Red Reinette. Described November 28. Fruit large, conical; skin greenish-yellow with a pink blush on sunny side; dots few, gray, not prominent; cavity deep, narrow, much russetted; stem short, moderately stout; basin medium depth and width, slightly wrinkled; calyx large, open; flesh yellow, crisp, tender, moderately juicy, pleasant flavour, brisk sub-acid; core, medium size; skin, thick, moderately tender. Good quality. Season, November. One of the best of the Russian varieties.

Three varieties have been found under the name of Melonen. First, that described as a synonym of Liveland Raspberry in the report for 1898, and two others, quite distinct.

RUSSIAN APPLE SEEDLINGS.

It was reported last year that 1,016 of the Russian apple seedlings were still living. This year 118 of the poorest shaped and least vigorous trees were removed to give more space to those remaining. A number of those which have fruited and have been found to be of little value will be cut out before spring. The number now remaining is 898.

It is surprising how vigorous and healthy the seedlings are, growing in apparently almost pure sand and not receiving any fertilizers; but the fruit which is produced on them partakes of most of the characteristics of the named Russian varieties, and although 133 have fruited during the past three years, 43 of which fruited this year, none of them are of sufficient merit to deserve special mention. A large proportion of them, however, seem just as good as most of the named Russian sorts which have been disseminated in this country. No late-keeping winter apples have yet been found among them.

TOP-GRAFTING.

Many of the best varieties of apples do not succeed at Ottawa; they are either subject to sun-scald, root-killing, or killing of the terminal branches. There are, however, other kinds of apples, possessing less commercial value, which are quite hardy and do not suffer from sun-scald. In 1896, four of these varieties, McMahan White, Gideon, Haas and Romna, were planted as stocks on which to top-graft some of the tenderer sorts, it being thought that some of them, at least, would succeed at Ottawa if grown in this manner. Top-grafting was begun on these stocks in the spring of 1898, and continued this year; the following varieties being successfully grafted:—Baldwin, Belle de Boskoop, Benoni, Dominie, Early Harvest, Esopus Spitzenburg, Fallawater, Keswick Codlin, King of Tompkins Co., Mother, Newtown Pippin, Northern Spy, Ontario, Rhode Island Greening, Rome Beauty, Sutton Beauty, Wagener, Winesap and York Imperial.

This work will be continued until all the best varieties of apples which are likely to grow here have been tested. The results of this work will be watched with much interest from year to year. To show the possibilities in this direction, it may be said that in 1891 a tree of Duchess and two trees of Wealthy were top-grafted with Northern Spy, which will not live on its own roots at Ottawa. All of these fruited in 1897. The grafts on Duchess produced fruit in 1897 and 1899, and those on Wealthy in 1897 and 1898. The wood of the Northern Spy appears quite hardy, and if the Duchess and Wealthy had been stronger growing stocks it is probable that good crops would have been produced for many years, but the Northern Spy is out-growing the stocks and soon the trees will be so top heavy that they will likely break off in a severe storm. It is, then, not wise to top-graft a strong-growing variety on a weak-growing stock.

There are so many apple trees of little value growing in Canada, which could be successfully top-grafted with better varieties, that it would well repay any one possessing an orchard to go carefully over his trees and top-graft those which do not produce paying crops. A circular on top-grafting was published by the Experimental Farm a few years ago which can be had on application, in which the methods employed in top-grafting are clearly set forth. The chief points to take into consideration in top-grafting may be briefly summarized from the circular, thus :—

1. Old trees, if healthy, may be grafted with success.

2. The top should not be all cut away the first year, but should be removed gradually, the time required to change the top of a large tree successfully being from three to five years.

3. Early spring, before growth begins, is the best time to graft.

4. The branches to be grafted should not be more than from 2 to 3 inches in diameter where the grafts are to be inserted.

5. After the branch is carefully sawn in two, the stub is split with a mallet, held open with a wedge, and the scions inserted ; two being used, one on each side, if the branch is more than an inch in diameter.

6. The scion is made from a twig of the previous year's growth, about 4 or 5 inches long and having three or four buds. It is prepared by making a wedge of the lower end, beginning near the base of a bud. The scion is inserted in the stock as far as the upper edge of the wedge.

7. In inserting the scion, great care should be taken that the inner bark of both scion and stock should come in contact with each other. This is very important, as the healing begins from this point and if the scion is inserted carelessly there is almost certain to be a failure.

8. After the scion has been set, the cut surface is covered over with grafting wax to exclude air, and strips of cotton may be wrapped over this.

9. A good grafting wax for outdoor use is made by melting together resin and beeswax in the proportion of five parts resin and two parts beeswax ; to this is added one and one-half to two parts linseed oil.

10. In top-grafting a tree, always have in view the production of a symmetrical top after the old one has been removed.

PEARS.

The pear trees were very little injured last winter, and during the past summer they made good growth. A few varieties fruited, but none of these were of special merit, being, most of them, inferior sorts of Russian origin. No blight appeared in the orchard. The Russian pears have proved the hardiest at the Experimental Farm, and advantage has been taken of this fact to top-graft them with some varieties of better quality. This work was begun last spring, and the following kinds were successfully grafted :—

Angouleme, Bartlett, Clairgeau, Clapp's Favourite, Gansel's Bergamot, Dr. Jules Guyot, Duhamel du Monceau, Emile d'Heyst, Madame Treyve, Knight's Monarch, Pitmaston Duchess, St. Swithin, Seckel, Smith's Hybrid, and Vicar of Winkfield. As there are no pears of first class quality which are hardy at Ottawa on ordinary pear stocks, it is hoped that by top-grafting them on Russian stocks a few may succeed here, but as the Russian pears sometimes kill out here, they are also liable to be lost at any time. It is proposed this winter and next summer to use European mountain ash and a wild pear from China called *Pyrus betulaefolia* as stocks, as these are hardy at Ottawa, and tender varieties grafted or budded on them may succeed. Any plan that will be likely to cause the best pears to fruit at Ottawa will be tried, in the hope that sometime success will crown our efforts.

PLUMS.

It is only a few years since nearly all the trees in the plum orchard were winter-killed, but the dead trees have all been replaced and the orchard now looks well.

Very few trees were injured last winter, and most of them made strong growth during the past summer. There was only a light crop of fruit, but forty varieties bore this year. These were, however, nearly all American sorts. The aphides were not troublesome this year, but the shot-hole fungus riddled the leaves very badly, notwithstanding the thorough sprayings which the trees received. It is supposed by some that spraying increases the disease, but it was bad on trees that were not sprayed.

Of the varieties of American plums which fruited this year, the following, given in their order of ripening, were the most promising:—

Bixby, ripe Aug. 31; Cheney, ripe Sept. 2; New Ulm, ripe Sept. 6; Ocheeda, Wolf, City, Cottrell, ripe Sept. 14; Stoddard, Wyant, ripe Sept. 19; Comfort, DeSoto, ripe Sept. 25.

The Aitkin plum, which ripened on August 22, is a fine large red plum, but is only of medium quality. It may be planted with advantage on account of its earliness.

CHERRIES.

A few more of the old trees died this year, and there are now not many of them left. The trees of the Koslov Morello cherries were not as vigorous as usual, and had evidently been injured more or less last winter. All the young trees available in the nursery were utilized this year to fill up the blanks which still remained after the destructive winter of 1895–96. There were 133 trees planted, comprising twenty-one varieties. Nearly all of these are grafted or budded on bird cherry (*Prunus pennsylvanica*) stock. There was practically no fruit this year.

GRAPES.

This was a very unfavourable season for grapes. A wet July seemed to favour the growth of Anthracnose and many varieties were more or less affected by it. The whole summer was unfavourable to the rapid maturing of the fruit, and September was particularly so, being cold, cloudy and wet. A frost which occurred on September 23 did considerable damage, while another much more severe on October 2 killed the leaves on the vines and ruined a large quantity of fruit which was not sufficiently mature to harvest. While 130 varieties ripened in 1898, only sixty were fully matured this year. It was very interesting to note the date of ripening of the different sorts this year, as some which matured early last season did not ripen this year until late, thus showing which varieties would ripen early, even though the season were unfavourable, and those which require a greater amount of heat. In the report for 1898, a list was given of twenty-five of the earliest varieties for that year, in the order of their ripening. The following list of the twenty-five earliest this year will be interesting for comparison:—

Twenty-five earliest ripening varieties of Grapes 1899:

Florence, Sept. 7; Champion, Golden Drop, Sept. 17; Moore's Early, Sept. 21; Brant, Sept. 22; Moyer, Peabody, Canada, Pattison, Janesville, Telegraph, Sept. 23; Eumelan, Sept. 25; Belvidere, Hartford, Sept. 26; Early Victor, Cottage, Rogers No. 5, Northern Muscadine, Sept. 27; Marion, Requa, Maxatawney, Dracut Amber, Rogers No. 24, Sept. 29; Clevener, Sept. 30; Potter, Oct. 2. Of these, Florence, Northern Muscadine, Maxatawney and Dracut Amber are not desirable.

The cover crop of clover which was in the vineyard last winter was ploughed under on May 15, and the soil kept cultivated throughout the early part of the season. A large amount of old wood was removed from the vines this autumn and where possible new arms were obtained. It will take several seasons to renew all the vines, as it is difficult to get the required amount of wood in the proper place, and many of the vines do not sucker readily. The vineyard received a dressing of wood ashes and kainit last spring, part of the vines receiving the former at 100 bushels per acre, and part of the latter at 1000 pounds per acre.

CURRANTS.

There was a good crop of currants this year and all the bushes grew well. Some of the newer varieties began to fruit and a few of them give promise of being valuable, but it is too soon yet to pass judgment upon them. Cuttings were taken of all the varieties this autumn, looking forward to the making of a new plantation in 1901.

In the following tables will be found the yields of the different varieties during the past season, and other notes regarding them.

CURRANTS—RED.

RASPBERRIES.

It was reported last year that the raspberry plantation was not in a condition to make reliable comparisons of the different varieties being tested. It has improved somewhat in this respect this season, though there are still quite a number of varieties where the plants are not yet all in full bearing. As many as possible of the vacancies were filled this year, though the work is not yet complete. In a collection of so many varieties, it is very difficult to have them all in the right condition for accurate comparisons of yields. Most of the plants came through last winter well.

In 1895 a bulletin was published on raspberries, in which the results obtained with the different varieties up to that time were given, with information also as to the best methods of growing this fruit. This bulletin may be obtained on application by those who desire to know which are the best varieties to plant. Few good varieties have been introduced since that time. The Loudon raspberry, which is one of the best of the newer red varieties, will probably not prove superior to the Cuthbert. The Columbian, a purple variety, is very promising and may take the place of Shaffer's Colossal.

GOOSEBERRIES.

Only the American varieties of gooseberries have hitherto succeeded at the Experimental Farm. The European sorts are always so badly mildewed that what little fruit remains on the bushes is practically useless. In order to see if change of soil would have any effect on them, all the varieties, both American and European, were layered in 1898, the object being to start a new plantation on heavier and moister soil. Last spring the plants were set out. The American varieties which were layered had made good roots, but the European, as was expected, had in many cases only a few fibres. The old bushes, however, were divided where the layers were not sufficiently rooted, and a plantation was made consisting of twenty-nine American and ninety-five European varieties. The former made good growth, but the latter, though well sprayed, made very little; they will, however, be given a thorough test under these new conditions, and better results may be expected from some of them. Owing to the layering of so many of the bushes it is not possible to give yields of the different varieties. Downing, Pearl, and Red Jacket are still the leading American sorts, though some of Dr. Wm. Saunders' newer seedlings are very promising.

STRAWBERRIES.

This has been a very good season for strawberries in the Ottawa Valley, the crop being good and the prices high. It has given a great impetus to the growing of this fruit here, and a much increased acreage will be planted next spring.

A new strawberry plantation was made at the Farm this year, consisting of 350 varieties. Many of these will be discarded after one year's fruiting, as they have already been tested here, but we are not yet familiar with all of them, and it is desired that they may be studied and notes taken of them before they are no longer available. The soil used for this plantation is a good sandy loam which had been planted with potatoes in 1898 and ploughed shallow in the autumn of that year. In the spring of 1899 well rotted manure was applied at the rate of 30 tons per acre, the land was then ploughed just deep enough to cover the manure, and then disc harrowed twice, once lengthwise and once crosswise, in order to get the manure well incorporated with the soil. It was then rolled with a heavy land roller. The rows were marked off 3½ feet apart with a corn marker and twenty-four plants of each variety planted with a trowel, 15 inches apart in the rows, each variety occupying two rows of twelve plants each. No fruit was allowed to ripen this year, and no runners were permitted to grow until July. The soil was kept thoroughly cultivated and hoed throughout the season. Owing to about six weeks of dry weather during the month of August and the first half of September there were not as many runners formed as one would have liked, but there

are enough to promise a good crop of fruit next season. A light covering of straw was spread over the plants on December 16.

It is the intention to make a new plantation at least every two years hereafter. For commercial purposes it is the best practice to only take off one full crop and then plough the plants under.

As the old plantations had been bearing for several seasons, the varieties this year could not be fairly compared, and hence no table of yields is given.

Some of the best berries now on the market are Clyde, Glen Mary, Wm. Belt, Bubach, Greenville, Haverland, Lovett, Brandywine. The Sample, from all accounts, is a very promising new berry, but this has not fruited here yet.

A NORTHERN EXPERIMENTAL ORCHARD.

(SECOND REPORT.)

In the report of the Horticulturist for 1895, there was published, under the heading 'A Northern Orchard,' the results obtained by Mr. J. C. Chapais, St. Denis, Que., in testing large and small fruits at his place. As it is believed that the information given at that time has proven very useful to intending planters along the lower St. Lawrence, it has been thought wise to again publish a list of the trees tested by Mr. Chapais, as, after the last list appeared, many of the varieties, then doing well, succumbed to the severe winter of 1895-6, and it is important that fruit growers should know which were killed and which survived.

We are very grateful to Mr. Chapais for furnishing us with these notes, which, we know, will be appreciated by those whose climatic conditions are similar to his own.

Owner.—J. C. Chapais.

Locality.—St. Denis, County of Kamouraska, Province of Quebec, Canada.

Latitude.—47° 30′.

Lowest Temperature.—30° below zero Fahrenheit, experienced only twice in thirty six years.

Highest Temperature.—94° Fahrenheit.

Rainfall.—Average for twenty years, 29½ inches per year, including snow fall; 10 inches of snow estimated to equal 1 inch of rain. The average thickness of snow is 3 feet in open country.

Exposure.—Ground gently sloping to the north.

Soil.—Sandy clay, well drained.

Predominant Wind.—North-eastern damp wind, with salt emanations from the Gulf of St. Lawrence.

After the severe winter of 1895–6, which killed so many fruit trees, it was decided not to re-plant the following varieties of fruit as they were not promising.

Apples.—Antonovka, Blushed Calville, Charlottenthaler, Gipsy Girl, Golden White, Grand Duke Constantine, Louis' Favorite, Summer Arabka.

Pear.—Baba.

Plum.—Shropshire Damson.

Raspberries.—Japanese Wineberry, Stone's Hardy.

On the other hand, there are in the present list a number of varieties which had not yet been planted in 1895 and which are now being tested. The following is a list of these :—

Apples.—Ben Davis, Canada Baldwin, Canada Red, Grimes' Golden, Mann, Montreal Beauty, Ontario, Pewaukee, Red King, Salome, Wismer Desert, Wolf River, Yellow Transparent.

Plums.—Blue Imperial, Grand Duke, Gueii, Niagara, Pond's Seedling, Reine Claude de Bavay, Saunders, St. Cloud, Washington, Western Seedling, White Damson.

Cherries.—Dyehouse, Empress Eugénie, Ostheim, Windsor.

Currants.—Champion, North Star, Victoria.

Gooseberries.—College, Columbus, Golden Prolific, Keepsake, Lancashire Lad.

Blackberries.—Taylor.

Raspberries.—Golden Queen.

In this orchard, now planted for ten years, experience has shown, through many very bad seasons that the following varieties are *iron clad*, that is, most hardy and to be recommended in every respect for the north-eastern region of the Province of Quebec, such are :

Apples.—Alexander, Duchess of Oldenburg, English Golden Russet, Fameuse, Grandmother, Hare Pipka, McIntosh Red, Peach of Montreal, Red Astrachan, St. Lawrence, Titovka, Transcendent and Whitney.

Plums.—Blue Damson, Early Yellow, Reine Claude de Montmorency and Trabische.

Cherries.—Early Richmond, or French Cherry, on their own roots.

Small Fruits.—Almost all those mentioned in the general list given above.

ANOTHER NORTHERN ORCHARD.

The following is a report of another northern orchard, namely, that of Mr. W. Tremblay, Chicoutimi, Que. This report was read before the Quebec Pomological Society at its meeting in Montreal last winter. Mr. Tremblay lives in a very rigorous climate, where the temperature frequently falls to 38° F. below zero, and the information he gives of the success which he has had in growing and fruiting apples there should be of great value to those in his latitude in the Province of Quebec who may be contemplating the planting of fruit trees.

Latitude of Chicoutimi	48° 26′ Fahr.
Lowest temperature	38° Fahr, below zero.
Highest "	104° Fahr, above zero.
Climate	Very moist.
Snowfall	2 to 3 feet.
Situation of orchard	Surrounded by rocks, covered with trees, except on east side.
Soil	Sandy loam with clay subsoil, well drained.

'CHICOUTIMI, January 5, 1899.

'My first work dates from 1893. In that year I planted a Duchess apple tree and a Bradshaw plum ; the latter perished the following winter, but as the apple tree wintered well, I planted in the spring of 1894 three dozen apple and crab trees, comprising the following varieties :—Hyslop, Duchess, Yellow Transparent, Russian Transparent, Peach of Montreal, Red Astrachan, St. Lawrence, Golden Reinette, and Grimes' Golden, the two last named varieties not wintering well. I am testing some other varieties and to-day, notwithstanding a temperature every year nearly as low as 40° F. below zero, there are not less than twenty varieties succeeding in my orchard. Duchess, Yellow Transparent, Irish Peach, Winter Calville, Tetofsky, Hyslop, and Queen's Choice produced fine fruit in 1898.

'The winter of 1896–7 was exceptionally hard on fruit trees in this part of the province. Notwithstanding this fact, I did not loose a single tree during that winter, the growth of the previous year and the fruit buds, only, perishing. I have proven that a good number of varieties can stand a temperature of 40° F. below zero if the roots of the trees are well protected. It is first necessary, however, to let the ground

freeze to a depth of four or five inches. It sometimes happens, however, as was the case this year and last, that the snow falls before the ground freezes. It is then necessary to shovel the snow away and permit the ground to freeze to the required depth. Some snow and straw should then be placed about the base of the tree which will prevent alternate thawing and freezing before the fine weather comes in the spring. If the ground is thus kept frozen there is no danger of winter-killing. It is true that I have lost some trees, but this was more due to my neglect in not taking the proper precautions than to lack of hardiness of the trees.

'The following are the names of the varieties which are at present growing in my orchard:—Duchess, Yellow Transparent, Russian Transparent, Peach of Montreal, Irish Peach, Wealthy, Tetofsky, Scott's Winter, McIntosh Red, Wolf River, Winter Calville, Red Astrachan, McMahan White, Gideon, Lawver, Pewaukee, Ben Davis, Fameuse, Longfield, and Hyslop.

'I have lost the following varieties:—Northern Spy, Twenty Ounce, Canada Baldwin, and Golden Reinette.

'In conclusion, I think that it is possible to cultivate fruits very far north in our province, providing the roots of the trees are well protected, and that the soil remains frozen hard until after the first thaws in spring.

'I am now beginning to test some plum trees, in the hope of having similar success.

'W. TREMBLAY.'

SEEDLING FRUITS.

Owing, probably, to the fact that there were light crops of large fruits in most of the fruit-growing districts in Canada this year, the number of specimens received for examination was much less than last season. There has, however, come under our notice a few which are quite promising, descriptions of which will be found below. It is always gratifying to receive specimens from those who think they have a good variety of fruit, as by describing the best of them in this report it makes their existence known to fruit-growers and they can then be tested on a larger scale and their true value determined.

Record No. 176. Apple seedling 'Beauty of Norton': Tested Nov. 18, 1899:—from Mrs. H. K. E. E. P. Baker, Kentville, N.S.

Description.—Very large, roundish, conical; skin pale yellow, splashed and washed with red, mostly on sunny side; dots few, pale, obscure; cavity deep, open; stem short stout; basin deep and narrow; calyx open. Flesh yellow, tender, juicy, melting, mild sub-acid. Core, medium size; skin moderately thick, tender. Quality good; season November. Probably a seedling of Gravenstein. Mrs. Baker says that the tree was found growing near the railroad when about 4 feet high, and transplanted to its present position about fifteen years ago. It bears a good crop every year and is not subject to disease. It is good either for dessert or culinary purposes. The specimen received weighed 9½ ounces and measured 3½ by 3 inches in diameter. A specimen sent, but which was not received, was said to measure 14 inches in circumference.

Record No. 178. Apple seedling (No. 1.) Tested Feb. 4, 1899. From Asa Johnston, Cowansville, Que.

Description.—Medium size, roundish, slightly elongated, regular, smooth; skin yellow, almost covered with bright red; dots few, yellow, distinct; cavity shallow, narrow; stem short, stout; basin narrow, medium depth, smooth; calyx open. Flesh yellow, juicy, mild sub-acid, peculiar but not unpleasant flavour. Core small; skin moderately thick, tender; quality above medium. A very handsome apple and a good keeper.

Record No. 179. Apple seedling No. 2.) Tested Feb. 4, 1899. From Asa Johnston, Cowansville, Que.

Description.—Medium size, oblate, slightly conical; skin yellow, nearly covered with bright red; dots fairly numerous, yellow, distinct; cavity deep, open; stalk short, moderately stout; basin narrow, shallow, smooth; calyx partly open. Flesh yellowish, tender, juicy, sub-acid; core small, stem moderately thick, tough, quality good. A good keeper. Promising, Scions received 1899.

Record No. 181. Apple seedling. Tested Nov. 15, 1899. From R. Hamilton, Grenville, Que. Specimens taken from orchard of C. P. Newmann, Lachine Locks, Que.

Description.—Medium to large, oblate to slightly conical, ribbed; skin pale green, almost, and sometimes covered with dark red; dots numerous, small, yellow; cavity deep, moderately open, slightly russetted; stem short, moderately stout; basin medium depth and width; calyx closed. Flesh white, tinged with red near skin, moderately juicy, sub-acid, slightly astringent, pleasant but not high flavoured. Core medium size. Skin thick and tough. Quality above medium. Season, December and January. Scions asked for. From an old seedling tree in the orchard of C. P. Newmann, Lachine Locks, Que.

Record No. 184. Apple seedling 'de La Salle.' Tested Dec. 20, 1899. From R. Hamilton, Grenville, Que.

Description.—Above medium size, roundish, skin pale yellowish-green, splashed and washed with bright red and carmine, mostly on sunny side; dots few, gray, obscure; cavity deep, medium width, russetted; stem medium length, moderately stout; basin deep, wide, slightly wrinkled; calyx open. Flesh yellow, firm, crisp, juicy, sub-acid, pleasant flavour. Core medium size. Skin thick and moderately tough. Quality good. Season, January to May. Promising. Original tree stood on the farm of John Fraser near Lachine, Que. Scions asked for.

Record No. 187. Apple seedling 'Minto.' Tested Nov. 14, 1899. From J. P. Cockburn, Gravenhurst, Ont. Grown by Rev. Wm. Reeve, Gravenhurst, Ont.

Description.—Medium size, roundish, broadly ribbed; skin pale green, splashed and washed with dull dark red, mostly on sunny side; dots few, green, distinct, but

not prominent; stem short, moderately stout; cavity deep, narrow; basin medium depth and width, slightly wrinkled; calyx closed. Flesh white, crisp, tender, juicy, mild sub-acid, pleasant but not high flavoured; core medium size; skin moderately thick. Quality good. Probably season of Fameuse. Tree said to be about 10 years' old, very hardy, and an annual bearer. Not desirable where Fameuse and McIntosh Red will succeed, but if hardier than these trees it may prove valuable.

Record No. 189. Pear seedling. Tested Sept. 11, 1899. From Miss Lilian A. Trotter, Owen Sound, Ont.

Description.—Below medium size, obovate, obtuse pyriform; skin yellow with a pink blush on sunny side; dots numerous, small, brown; cavity broad and very shallow; stem medium length, stout; basin narrow, shallow. Calyx open. Flesh yellowish, moderately juicy, buttery, sweet, high flavour. Quality very good. A little over ripe at this date. Tree grown from seed by the late Richard Trotter, Owen Sound, Ont.; said to be a healthy, rapid grower. Fruited for the first time in 1898, when there was one pear. Fair crop in 1899. Promising. Scions received 1899.

Record No. 190. Peach 'Millionaire.' Tested Sept. 12, 1899. From E. D. Smith, Winona, Ont.

Description.—Large, roundish, skin rich yellow, with a purplish red blush on sunny side; suture shallow, obscure except near cavity, where it is distinct. Flesh yellow, very juicy, sweet, rich; stone medium size. Freestone. Quality very good. Season, immediately after Early Crawford. Promising.

SPRAYING.

The trees, shrubs, and plants were thoroughly sprayed this year as in previous years, as a result of which comparatively little injury was done by fungous diseases or insects. The Tent caterpillars and Forest Tent caterpillars which did so much damage to fruit trees in Ontario and Quebec this year, were killed here by spraying the trees with Paris green shortly after they were hatched and before they had done much damage.

EXPERIMENTS IN WHITEWASHING TREES.

In a bulletin prepared by Mr. John Craig, late Horticulturist of this farm, on 'Peach Culture in Canada' (Central Experimental Farm, Bulletin No. 1, Second Series, September, 1898), he quotes from a bulletin published by Prof. J. C. Whitten, Horticulturist at the Missouri Agricultural Experiment Station, some interesting results which were obtained at that station in preventing the swelling of peach buds by whitewashing the trees. As no experiments had yet been conducted here to corroborate the results obtained in Missouri, and as the winter-killing of the fruit buds of the peach is a matter which interests many of our own fruit growers, it was thought desirable that we should be in a position to state whether the results obtained by Prof. Whitten could be had here or not. To make the matter as clear and concise as possible, I cannot do better before giving the results of our experiments here, than quote Prof. Whitten's summary of his work from Bulletin No. 38, Missouri Agricultural Experiment Station:

'I....In this latitude, winter-killing of the fruit buds of the peach is usually due to the unfavourable effects of freezing after they have been stimulated into growth by warm weather, during winter or early spring.

'II....The early swelling and growth of the buds is due to the warmth they receive, is practically independent of root action, and may take place on warm sunny days in winter, when the roots are frozen and dormant.

'III....Peach fruit buds may safely endure a temperature of ten or twenty degrees below zero, providing they mature well in autumn, are entirely dormant, and the cold comes on gradually.

'IV....Zero weather may kill fruit buds that have swollen during previous warm weather, or that were not properly ripened in the autumn.

'V....Shading and whitening peach trees to prevent their absorbing heat on sunny days opposes growth of the buds and is, consequently, a protective measure.

'VI....Shading the trees with board sheds enabled peach buds to survive the winter uninjured, when eighty per cent of unprotected buds were killed.

Trees protected in this way blossomed later, remained in bloom longer, set more fruit in proportion to the number of apparently perfect flowers, and held their fruit better than any other trees on the station grounds. This is the most effective means of winter protection tried at the Station, but it is probably too expensive for commercial orchards.

'VII....Whitening the twigs and buds by spraying them with whitewash is, on account of its cheapness and beneficial effects, the most promising method of winter protection tried at this station.

'VIII....Whitened buds remained practically dormant until April, when unprotected buds swelled preceptibly during warm days late in February and early in March.

Whitened buds blossomed three to six days later than unprotected buds. Eighty per cent of whitened buds passed the winter safely, when only twenty per cent of the unwhitened buds passed the winter unharmed.

'IX....Thermometers covered with purple material registered, during bright sunny weather, from ten to over twenty degrees higher than thermometers covered with white material of similar texture, thus indicating that whitened peach twigs might be expected to abso rb much less heat than those which were not whitened.'

Not having any peach trees at Ottawa on which to try the experiment, the test was confined to plums, cherries and apples, the number of trees used being: plums five, cherries three, apples six.

The whitewash was made by using unslaked lime, skim milk, and water in the proportion of:

Skim milk....................................	6 gallons.
Water..	24 "
Lime...	60 lbs.

The lime was slaked in warm water and the remainder of the liquid added and the whole thoroughly stirred. It was then strained through an one-twelfth inch mesh and was ready for use. As the experiment was not on a very large scale, a hand pump was used with a Bordeaux nozzle, which worked very satisfactorily. The first spraying was given on February 16, and successive sprayings were made on February 21 and 25, March 1, 10, 13, and April 1, six in all, the object being to keep the trees pure white from top to bottom until warm weather came in the spring.

The following notes were taken at intervals from the latter part of the winter until warm weather:

Plums: April 5.—No apparent swelling of the buds on either sprayed or unsprayed trees.

April 15.—No apparent swelling of the buds on sprayed or unsprayed trees.

April 20.—Buds on unsprayed trees very slightly swollen; buds on sprayed trees still apparently dormant.

April 24—Buds on unsprayed trees of *Americana* class slightly swollen; on sprayed trees just perceptibly. Buds still apparently dormant on sprayed and unsprayed trees of *domestica* class.

April 28.—Flower buds on American plums now showing quite generally on unsprayed trees, a few flower buds showing on sprayed trees, but difference very decidedly marked; not so much swollen. Buds on unsprayed European plums just starting perceptibly; on sprayed trees, still apparently dormant.

May 2.—Flower buds now exposed in both sprayed and unsprayed trees, but difference more marked than before. Greater contrast in buds on unsprayed and sprayed trees of European plums. Buds on sprayed trees have only swelled slightly.

Temperature was above 80° F. on April 30 and May 1 and 2, causing rapid swelling of buds. Impossible now to keep buds covered with lime unless sprayed every day. Last spraying was given on April 30.

The dates of blooming of the plums sprayed and unsprayed were:

Jessie (American)	unsprayed	May 22
"	sprayed	" 24
Early Red (European)	unsprayed	" 13
"	sprayed	" 22

A considerable number of blossom buds on the Jessie plum were killed by the whitewash, but the plums on the sprayed trees were larger than on the unsprayed, and there was the same quantity of fruit on it as on the unsprayed tree. The two trees were about the same size.

There were only a few blossoms on both sprayed and unsprayed trees of the Early Red plum. There were about the same number of blossoms on both trees.

A tree of a hybrid between the Sand Cherry and the American plum in the Director's garden was sprayed with the whitewash and a considerable number of buds were killed by the wash.

Cherries: April 5.—Buds on unsprayed trees swollen very slightly; on sprayed trees still apparently dormant.

April 15.—Buds on unsprayed trees swollen slightly; on sprayed trees, still apparently dormant.

April 20.—Buds more swollen on unsprayed trees; on sprayed trees, starting to swell. A tree, part of which was sprayed and part unsprayed, has buds more swollen on unsprayed part than on sprayed part.

April 24.—Difference between sprayed and unsprayed cherry buds very apparent now.

April 28.—Still greater difference between sprayed and unsprayed buds, though sprayed have swollen considerably.

May 2.—Still a marked difference between sprayed and unsprayed.

There were no flowers on either sprayed or unsprayed trees. There was no apparent injury from the use of the whitewash on the trees.

Apples: April 5.—Buds apparently still dormant on sprayed and unsprayed trees.

April 15.—Buds apparently still dormant on sprayed and unsprayed trees.

April 20.—Buds on unsprayed trees very slightly swollen; on sprayed trees, still apparently dormant.

April 24.—Although buds were thought to be slightly swollen on the 20th, on unsprayed trees, no perceptible swelling is noticed to-day. Buds on sprayed trees still apparently dormant.

April 28.—Buds swollen slightly on both sprayed and unsprayed trees.

May 2.—Buds are still only slightly swollen on sprayed and unsprayed trees; no apparent difference.

The results here given are sufficient evidence of the fact that the retarding of the swelling of the buds was quite marked on trees of plums and cherries, but the difference in the dates of blossoming was very slight. A considerable number of the blossom buds of the plums were killed by the whitewash. As the buds on apple trees do not swell until late, the whitewash appeared to have little effect in retarding the swelling of them. I am not yet prepared to say whether it would be practical, beneficial, or advisable to spray peach trees to prevent the winter-killing of the buds.

EFFECT OF LIME ON THE OYSTER-SHELL BARK-LOUSE.

Notwithstanding the thorough sprayings which the trees in the orchard at the Experimental Farm receive, the oyster-shell bark-louse, which has infested the apple trees for several years, has never been entirely destroyed.

Last summer when the whitewash came off the trees which had been sprayed in the experiment to determine what effect whitewashing trees would have in preventing the swelling of the buds, we were surprised to find that the trees were practically free of the oyster-shell bark-louse. All the old scales had disappeared, the bark of the trees was brighter and cleaner, and they had all a healthier apperance than those under the same conditions but which had not been sprayed with whitewash. None of the whitewashed trees, however, had been examined for bark lice before they were sprayed, but considering the fact that the remaining seventy-two trees of Wealthy, thirty-one of Duchess, twenty-six of Tetofsky are all from slightly to badly infested with old scales there is, I think, ample evidence of the wonderful effect of the whitewash on this insect.

EXPERIMENTS WITH LIME IN PROGRESS.

Experiments are now in progress at the Farm with trees infested with oyster-shell bark-louse, and at Niagara on trees affected with San José and New York scales, to determine, if possible, the best time to whitewash the trees to get the best results, the number of applications necessary, how long before the whitewash takes effect, and any other points which may come up. It will be interesting to learn what effect lime will have on the San José scale.

The formula used this winter is:

6 gallons skim milk,
30 " water,
60 lbs. lime,
10 lbs. salt.

It may be found that a much thinner wash will be as effective; made by the present formula, it is very thick and has to be kept thoroughly stirred.

The use of lime in whitewashing the trunks and large limbs of trees is an old custom and still adopted by a few. It was supposed to have a generally beneficial effect on the tree, but I have not yet been able to learn just what effects it really had.

Lime was recommended by Forsyth in 1802 for the destruction of aphis and red spider. His formula was:

Unslaked lime	½ peck
Water	32 gallons

It was applied by means of a syringe.

Air-slaked lime is used successfully in destroying slugs on the foliage of trees.

Lime was recommended in 1850 against the Curculio of plums by Lawrence Young, Louisville, Ky., and it was said to have been used successfully by him. 'It consists simply in covering the young fruit as soon as danger is apprehended with a coating of thin lime wash, considerably more dilute than the mixture used in whitewashing.'

In Bailey's Horticulturist's Rule Book, we find lime spray recommended to prevent the attacks of the rose chafer. The formula reads: 'Slake ½ peck, or a peck, of lime in a barrel of water, straining the lime as it enters the barrel, to prevent its clogging the pump. Apply in a spray until the tree appears as if whitewashed.'

Messrs. H. Lutts & Son, Youngstown, N.Y., U.S., have been very successful in destroying the pear tree psylla by means of lime. I quote from a letter received from Mr. H. Lutts, dated December 29, 1899:

'Replying to your inquiry regarding our using whitewash for pear tree psylla, would say that we commenced using it on this principle, to destroy the brood that wintered over, believing that every adult that we destroyed we were gaining a great point, and after three years experimenting we believe we were right.

'Our plan has been to scrape off all rough bark any time in December when it is freezing, and the colder the better. We spread a canvas under the trees and save all the scrapings and insects and immediately burn all up.

'We then give the trees, as far up as we can, a good thorough coating of thin slushy whitewash, made of freshly slaked lime that has been run off in a putty state as masons usually hold it for plastering purposes, thin with skim milk. This we put on with a

brush; for the balance of the tree not reached with a brush we thin this same wash with milk, and spray the tree completely. We believe by this process to have accomplished two things: first, we have destroyed a larger proportion of the hibernating psyllas and many of those not destroyed are so well sealed up that they cannot escape to lay their eggs during the first few warm days of April. We spray again in March to coat the wood and buds over so thoroughly that when the few that are alive attempt to lay their eggs they will not find many favourable places. The orchard in which we have been thorough in has no signs of psylla in it now. We are confident that it is more effectual than kerosene or kerosene emulsion, both of which we have tried thoroughly. The orchard where we experimented contained 1,000 trees and was virtually ruined with psylla. Since we began using lime it has steadily regained its vigour, and to-day it will be hard to find its equal for brightness or apparent vigour. We do not like to recommend this to everyone as we believe much depends on the thoroughness of the scraping and the thorough whitewashing. Many that attempt to fight the psylla on those lines will fail, no doubt, but our trees tell us that the plan is all right, and we have given you the principal points and hope if you experiment you will favour us with your reports.

'Yours truly,

'(Signed.) HENRY LUTTS.'

Prof. J. C. Whitten, Horticulturist, Missouri Agricultural Experiment Station, informs me that limewash prevents peach curl.

No where have I found that trees have been whitewashed for the sole purpose of killing scale insects.

While the results obtained seemed to prove the value of lime as an insecticide, we do not advise using it extensively until further experiments furnish more data.

SPRAYING TO DESTROY OYSTER-SHELL BARK-LOUSE.

Last spring all the apple orchard with the exception of the trees which had been whitewashed, received two sprayings for the purpose of, if possible, destroying this pest. Careful watch was kept for the day when the young lice made their appearance, which was on May 29. On June 1, the trees received a spraying of tobacco water and whale oil soap, made by using 10 pounds tobacco and 2 pounds whale oil soap to 40 gallons of water. Specimens of the young insects were examined under the microscope and were found to be dead within an hour of the time they were sprayed. On June 6, the trees were sprayed a second time with whale oil soap, 8 pounds to 40 gallons of water. This was to kill all that were left. Although their numbers were greatly reduced, there must have been a considerable number escaped, as healthy scales were found in the orchard later in the summer.

'DRY ROT,' 'BROWN SPOT,' OR 'BALDWIN SPOT' OF THE APPLE.

In the report of the Horticulturist for 1896 some notes were published on 'A Dry Rot of Apples.' This apparent disease of the apple had been first brought under the notice of the Horticulturist in 1895, when it affected the fruit in the orchards at the Central Experimental Farm, and when specimens of diseased fruit were received from various parts of the Dominion.

As this dry rot was well described in the report for 1896, the same description may be used with advantage here:

'The disease was manifested exteriorly by small circular depressions on the surface or skin of the apple. These depressions were $\frac{1}{8}$ to $\frac{1}{4}$ of an inch deep and $\frac{1}{4}$ to $\frac{5}{8}$ of an inch in diameter. On removing the skin of the apple it was found that each depression was the centre of a small area of dryish brown tissue. In some varieties, badly attacked, this brown and pithy tissue extended in a more or less complete network over the whole

Apple Tree Sprayed with Lime Mixture, Central Experimental Farm, Ottawa.

Plantation of Tobacco, Central Experimental Farm, Ottawa.

surface of the apple. Its texture was dry and tough enough to prevent it from being cut into easily with anything but a keen edged blade. The flesh of the apple was rarely affected to a depth of more than ⅜ or ½ an inch. The affected flesh was dry and flavourless, but not bitter. While the apple was not rendered wholly unfit for use, its appearance and salability were totally destroyed.'

During 1897 and 1898 this dry rot has affected nineteen varieties of apples at the Experimental Farm, and some crops have been so badly injured that the fruit was almost all worthless. Although the trees have been thoroughly sprayed, the fungicides appeared to have no effect.

In order to get information which might lead to learning the cause of this rot—for up to this time no germs of disease which seemed to have caused this rot have been found by any bacteriologist, to our knowledge—a circular was prepared and sent out on October 25, 1899, to prominent fruit growers in many parts of Canada, and to the horticulturists of all the agricultural experimental stations in the United States. The following is a copy of the circular:—

EXPERIMENTAL FARM,
OTTAWA, October 25, 1899.

DEAR SIR,—I desire to obtain as much information as possible regarding a dry rot of apples (the same as is described in the report of the horticulturist for 1896, page 171), and should be much obliged if you would assist me by answering the questions enumerated below, if the disease has come under your notice.

The disease is indicated by small depressions on the surface of the fruit, under which the flesh is of a brownish colour. It frequently spreads throughout the apple, rendering it almost, or quite, worthless. It does not taste bitter (and in that respect there is a marked difference between it and the Bitter Rot), but the flesh becomes dry and flavourless.

1. For how many years have you observed this disease?...... 2. What varieties has it affected? ..... 3. Are the trees in a healthy condition?...... 4. Have you sprayed your trees thoroughly with Bordeaux mixture, and, if so, with what results as regards this disease?...... 5. What kind of soil are the affected trees grown in? Surface and subsoil?...... 6. How frequently do you fertilize your trees, and what fertilizer do you use?...... 7. What is your system of cultivation?...... 8. Do you think the soil contains all the necessary elements of plant food in a form made easily available?...... 9. What is your opinion of the cause of this disease?......

I shall be pleased to receive samples of affected fruit.

Yours very truly,

W. T. MACOUN,
Horticulturist.

In response to these inquiries, 63 replies were received, and a synopsis of the information obtained is given herewith:—

Number who have observed the rot, thirty-five.

Number who have not observed the rot, twenty-eight.

Length of time rot has been observed, twenty-eight years.

Number of varieties affected, sixty.

Provinces in Canada where rot has been observed: Nova Scotia, Quebec, Ontario, British Columbia.

Provinces in Canada where rot has not been observed: Prince Edward Island, New Brunswick.

States in the United States where rot has been observed: New York, Vermont, New Jersey, Maryland, Massachusetts, North Carolina, West Virginia, Pennsylvania, Michigan, Minnesota, Maine.

States in the United States where rot has not been observed: Alabama, Louisiana, New Mexico, Arkansas, Arizona, Oklahoma, Indiana, Missouri, Iowa, Wyoming, Montana, California and Oregon.

Provinces in Canada where disease appears to be most prevalent : Ontario (Eastern), Quebec, British Columbia.

States in the United States where disease appears to be most prevalent: New York, Vermont, New Jersey, Maryland.

Causes assigned by growers :—

1st.—Want of vigour of tree.
2nd.—Want of moisture in soil.
3rd.—Fungous disease.
4th.—Want of potash and lime in soil.

Causes assigned by bacteriologists :—Physiological.

Samples of affected fruit have been submitted to Dr. Connell, Queen's University, Kingston, Ont., who has given this rot considerable study. He could not find any ungus which appeared to cause this rot.

Prof. L. R. Jones, Botanist of the Vermont Agricultural Experiment Station, who has given more attention to this subject than, perhaps, any other man in America, and who published some information regarding it in 1891, has recently published the results of his latest investigations which, while seeming to prove that the trouble is physiological, do not yet make it clear as to why the rot should occur.

The following are some quotations from his report, which give some information not found in the report for 1896 of the Horticulturist of this Farm :—

Re-examination of these brown spots has been made by us on various occasions since our earlier publication. In most cases, especially in the autumn and early winter, no fungus has been detected in the browned tissues, and it has, therefore, become evident to us that the spotting was not primarily a fungous disease.

Having opportunity at this stage of the study to confer with the officers of the Division of vegetable physiology and pathology of the United States department of agriculture it was learned that Mr. M. B. Waite and Dr. E. F. Smith had made observations upon a similar spotting of apples which they were satisfied was a non-parasitic disease and which Dr. Smith considered identical with a dry spot disease described by Wortmann as occurring in Europe.

The examination of Wortmann's paper[1] leaves no doubt that the disease discussed by him under the name "Stippen" or "Stippich-werden" is identical with the brown spot of the Baldwin, although the Baldwin did not chance to be among the varieties included in his studies.

Wortmann's work has been recently critically reviewed and his conclusions re-affirmed and somewhat extended by Bschokke.[2] Numerous experiments were devised and conducted by Wortmann and others by Bschokke in connection with their studies which satisfied them of the correctness of their conclusions.

1 Wortmann, Ueber die sogenannte, "Stippen" der Aepfel. Landw. Jahrb., 21, pp. 663-675 (1892).

2 Bschokke, Landw. Jahrb. d. Schweiz, 11. pp. 192, (1897). This author gives a very complete bibliography of the German literature of the disease.

Occurrence.—The trouble is of widespread occurrence both in Europe and America. It is worse on some kinds of apples than on others; and upon the same kind its occurrence varies with climatic or cultural conditions, and probably with those of storage. Wortmann states that large, sappy varieties and specimens are most liable to spot.

The variety pre-eminently subject to it in the Northern United States is the Baldwin. It has already been stated that it is of frequent occurrence on Northern Spy, in Vermont, and not rare on Greenings. Selby records the occurrence of the Baldwin spot in Ohio and also that of a brown spot on Northern Spy and other varieties.

Wortmann records the trouble as occurring in varying degrees upon numerous varieties in Europe as follows: Red Reinette, Golderling, Woltman's Reinette, Hawthornden, Winter Pearmain, Landsburger Reinette, Stettin, Dantziger.

Cause.—Neither fungi nor bacteria are to be found in the earlier stages of the spot formation nor is there a constant occurrence of any such organism in the latter stages. It is therefore a non-parasitic disease

Wortmann's observations and experiments lead him to conclude that the death of the cells in these spots is a result of the concentration of the sap following the loss of water. This water may be lost by direct transpiration in the case of the superficial cells, or in case of the deeper cells by excessive conduction of the water to the transpiring surface layers. The acidity of the concentrated sap is considered to be the direct cause of the injury, this injury being followed by the browning through oxydization.

Several factors may therefore enter into the problem of spot formation.

1. The amount and rapidity of transpiration. This is dependent upon the character of the epidermis, conditions of storage, etc. The fact is emphasized that *gradual* loss of sap is essential to the formation of typical spots. Thus a specimen of a variety which is subject to spot will shrivel without the appearance of spots if kept in a warm dry room. Wortmann suggests that in case of such very rapid loss of water the acid of the concentrated sap has insufficient time to act.

2. The kind and relative amount of substances in solution in the cell sap. The same degree of concentration of different solutions may not be equally injurious, hence the actual per cent of water lost in spotting and non-spotting varieties may not stand in a direct relation to their susceptibility to the disease.

3. The conductivity of the tissues of the fruit. The original loss of water must always occur at the surface. The death of these surface cells may ultimately follow unless this loss is made good by the conduction to them of water from the underlying tissues. In some varieties this conduction occurs more rapidly than in others. Wortmann found that in varieties subject to spot there was relatively slow water conduction.

Bschokke considers this relative rate of water conduction to be the most important factor in deciding the susceptibility of a given variety to the spot disease.

4. The specific resistance of the protoplasm of the cells to the injurious action of the concentrated sap. This is probably greater in some varieties than in others, and it may vary also with climatic and other cultural conditions.

Remedies.—Wortmann concludes that the spotting of susceptible varieties cannot be prevented entirely, but that, since trees which are improperly cared for produce fruit of less resistance toward unfavorable influences of every sort, proper attention to fertilization and general cultural conditions is called for. He believes that moist cloudy weather, which decreases starch formation, favors the disease and that in seasons where such weather predominates an excess of nitrogenous fertilizer is especially unfavorable. He recommends a dry sunny exposure and pruning so as to admit sunlight. On theoretical grounds he believes that storage in a moist atmosphere with uniformly low temperature will lessen the development of the spots He also suggests the probable protection which would come from wrapping the apples separately in paper to check transpiration.

Bschokke revives a suggestion from the older literature that, since apples which have lost a considerable moisture from their superficial tissues by rapid evaporation do not spot, some treatment involving this method might be employed in bad cases. It is doubtful if this will commend itself in actual practice, although it has some theoretical interest.

Lamson finds that spraying Baldwins with bordeaux mixture—about as recommended for the scab fungus—reduces the amount of spotted fruit to a remarkable degree.

*The following is a summary of his results :

Prevention of brown spot of Baldwin by spraying with bordeaux mixture.		Per cent of spotted fruit Sprayed	Unsprayed.
1895	Sprayed once before and twice after blossoming	3	55
1896	Sprayed once before and once after blossoming	10	68
	Sprayed once after blossoming	18	68
1898	Sprayed once before and twice after blossoming	22	52

These results are certainly very striking. In view of the above explanations of the cause of this disease the question of why spraying should check the tendency to spot becomes a matter of a considerable practical as well as theoretical interest.

CONCLUSIONS REACHED THUS FAR.

1. The Dry Rot, "Brown Spot," or "Baldwin Spot" affects at least 60 varieties of apples, and is thus not confined to only a few sorts. The Baldwin appears to be worse affected, but this may be due to the fact that it is grown more extensively than any other variety in those parts where the rot is most prevalent.

2. Its range extends from the Atlantic to the Pacific ; it appears, however, from data received, not to be found in Prince Edward Island, New Brunswick, and the southern and south-western States, although it may be there also.

3. It appears to be most prevalent in Eastern Ontario, Quebec, British Columbia and the Eastern States.

4. Opinions of growers differ very much as to the cause of the rot.

5. The results of the investigations of Jones, Wortmann and Bschokke seem to throw most light on the cause of the rot.

6. No remedy has yet been found for this trouble.

Acknowledgments :—In addition to all the fruit growers who have been good enough to furnish me with information regarding the dry rot, I am much indebted for valuable information to Dr. Connell, Kingston, Ont. ; Prof. L. R. Jones, Burlington, Vt., US. ; Prof. C. O. Townsend, College Park, Md., U.S., and to Mr. F. C. Stewart, Geneva, N.Y., U.S., who have made microscopical examinations of this rot.

COVER CROPS.

Since 1895, orchard cover crops have received much attention at the Central Experimental Farm, and in the reports of the Horticulturist for 1896, 1897 and 1898, considerable space has been devoted to this subject; but the importance of cover crops in the orchard cannot be too often nor too strongly impressed upon the fruit growers of Canada. After the disastrous effects of last winter on fruit trees in some parts of Ontario, the fruit growers living in those districts must realize more than ever before, perhaps, how necessary it is to have some protection for the roots of their trees.

It is now quite generally conceded that cultivation should cease in orchards in Eastern Canada about the middle of July. At this time the season's growth is well advanced and the ripening of the wood soon begins. The seed which is to produce the future cover crop should now be sown. In Eastern Ontario, the common red or mammoth red clover, sown broadcast at the rate of 12 pounds to the acre, will probably make the most satisfactory cover crop. It will reach a height of from 10 to 12 inches by winter, and will form a dense mat of foliage which will make a thick mulch, thus preventing the alternate freezing and thawing of the ground which occurs in late winter or early spring, and which often proves so disastrous to trees. After the seed is sown, the soil should be rolled with a heavy land roller, which will cause the moisture to rise to the surface of the soil and assist the germination of the seed. This rolling is very important, as should the seed lie in the ground for any length of time without germinating, there will not be time for a good cover crop to be formed before winter. No nurse crop is, as a rule, necessary. In places where the soil is very dry, lucerne or alfalfa might be sown with advantage, as the seed of this clover appears to germinate more readily than that of the common red clover. Cow peas and crimson clover may be used in the warmer parts of the country.

Another advantage of clover growing in an orchard in autumn, is that much of the plant food in the soil which has been liberated and made more easily available by the constant cultivation during the early part of the summer, is prevented from leaching by being used by the growing plants, the clover thus becoming a 'catch crop,' as well as a cover crop.

Where soils suffer from lack of moisture in a dry time, the clover should be ploughed under as early in the spring as the land can be worked, and cultivation begun at once. This will conserve much of the moisture which would otherwise be transpired through the leaves of the growing plants until they were ploughed under towards the end of May, which is the usual time. If the soil, however, always contains plenty of moisture, it would be better to let the clover grow until about the third week of May, as there would be additional humus and nitrogen obtained by this method.

The great improvement made in the soil by the annual ploughing under of clover crops is clearly shown in figures given by Mr. G. T. Powell, Ghent, N.Y., U.S., at the last annual meeting of the Ontario Fruit Growers' Association. After crimson clover, which had been used as a cover crop—had been ploughed under in an orchard for three years, the soil was analyzed and the following differences were found between that where the clover had and had not been ploughed in:—

	Clover ploughed under for three years. Per cent.	No clover ploughed under for three years. Per cent.
Water............	15·00	8·75
Nitrogen..........	·21	·12
Humus..........	2·94	1·91
Phos. acid..........	·015	·008

The gain per acre would be:—

Water	6·25 per cent	=46,875 tons.
Nitrogen	·09 "	= 1,350 lbs.
Phos. acid	·007 "	= 105 lbs.

Although such good results might possibly not be secured by the use of red clover, still the improvement in the land by such treatment would be very great.

For the reasons mentioned in my report for 1898, the methods which are recommended above have not been adopted at the Central Experimental Farm since the spring of that year. Clover is used for a cover crop, but it is only ploughed under every two years. As the soil here is light and lacking in humus, but apparently contains plenty of moisture, a system of cutting the clover with a field mower and leaving it to rot in the orchard, has been followed. In 1898 five cuttings were obtained, the clover being from eighteen to twenty inches high at each cutting and just coming into bloom. It was estimated that from the first four cuttings 25 tons per acre of green crop were left lying on the field. Clover sown in 1898 was cut four times this year, and the crop from each cutting appeared fully as good as that of last year. It can easily be imagined that this is improving the soil rapidly.

Common Red Clover was sown in the orchards this year on May 10, 17, 25 and 31; July 4, 11, 18 and 25. There was a good cover crop obtained from all of these sowings, with the exception of that on May 31, which did not germinate well, and from those of August 2, 9 and 16 at which time the weather was very dry and the seed did not germinate until September, and then but thinly. Clover sown on May 17 and 25, was nearly smothered by purslane, but eventually overtopped it and came on well and formed a good cover crop by autumn.

In a part of the apple orchard where the soil is very poor, two green crops were ploughed under this summer. On June 10, clover which had formed a cover crop the previous winter was ploughed under and the land was then re-sown with buckwheat, soja beans, English horse beans and field pease, with the following results:—

Buckwheat sown broadcast on June 17, at the rate of 2 bushels per acre; came up June 23. Ploughed under on July 25. Average height 27 inches. Estimated yield per acre of green crop: 8 tons 335 pounds.

Soja Beans:—sown in drills 6 inches apart on June 17, at the rate of 3 bushels per acre, came up June 24. Ploughed under on August 7. Average height 14 inches. Estimated yeield per acre of green crop: 3 tons 466 pounds.

English Horse Beans:—Sown in drills 6 inches apart on June 17, at the rate of 4 bushels per acre, came up on June 27. Ploughed under on August 7. Average height 18 inches. Estimated yield per acre of green crop: 6 tons 592 pounds.

Field Pease:—Sown in drills 6 inches apart on June 17, at the rate of 3 bushels per acre, came up on June 24. Ploughed under on July 29. Average height 26 inches. Estimated yield per acre of green crop: 5 tons 1,191 pounds.

After these crops were ploughed under the land was re-seeded with clover on August 2, 9 and 16, in the hope of getting a cover crop by winter, but owing to nearly six weeks of very dry weather about that time the seed did not germinate until September and a cover crop was not formed. The trees in this part of the orchard have been mulched with manure.

On July 6, English horse beans were sown in a part of the orchard where the soil was light and where the snow does not lie well in winter. On July 16, after the beans were up, common red clover was sown among them at the rate of 12 pounds per acre. The beans reached a height of 18 inches by autumn and helped very much to hold the snow while they must have gathered much nitrogen during the growing season. There is also a good stand of common red clover.

On July 25, Lucerne clover was sown in a part of the orchard where the soil was very light. It reached a height of from 7 to 12 inches by autumn, and although there was a large number of plants destroyed by a storm carrying away the surface soil, there is a fairly good cover crop.

RELATIVE DATES OF BLOSSOMING OF DIFFERENT VARIETIES OF APPLES.

During the past five years the dates of blossoming of large and small fruits have been recorded by a large number of observers in different parts of Canada for this

Division. In 1895, Mr. John Craig, then Horticulturist of the Central Experimental Farm, inaugurated this work. The following circular, which was sent out by Mr. Craig to those whom he asked to assist him states clearly the reasons why the information he desired to get should prove of much value to fruit growers throughout Canada :—

"Dear Sir :—The cause of the unfruitfulness of some varieties of large and small fruits when planted in large blocks by themselves is now understood to be due to self-sterility, complete or partial, causing imperfect pollination and fertilization. The remedy is the intermingling of varieties in the orchard for the purpose of securing cross-fertilization. To obtain the best results, the varieties adjacent to each other should blossom at or about the same time.

Accurate information with regard to time of the blossoming of the different varieties of fruit is much needed. Will you assist in securing data on this important subject?

Please observe and record dates as follows :—The time of the opening of the first blossoms ; when the tree is in full bloom ; also, the date of the fall of the blossoms ; and forward your records to me at the close of the season.

In his Report for 1895, Mr. Craig gives some of the data obtained that year, and makes some useful comparisons of the time of blooming of different varieties.

It was thought desirable that five years' records should be obtained, so that a fair average of the relative dates of blooming of the different kinds of fruit could be had. Five years' records have now been taken, but the data accumulated are so great that it is impossible to publish it all in this Report ; hence, it has been found necessary to publish only what is thought to be of greatest value to the intending planter, namely, the relative time of blooming of the different varieties. As all the kinds of fruit of which the dates of blossoming have been recorded cannot be treated of this year, it has been thought advisable to publish only the conclusions reached regarding apples. If information is desired about other fruits before the results are published, or if more information is wanted about apples, it may be obtained by correspondence.

EARLY GROUP.

Antonovka, Duchess of Oldenburg, Early Harvest, Fameuse, Gravenstein, Gideon, Haas, Hurlbut, Longfield, Patten's Greening, Red Astrachan, Scott's Winter, Shiawassee Beauty. Tetofsky, Wagener, Scarlet Pippin.—16 varieties.

MEDIUM GROUP.

Alexander, Baldwin, Baxter, Ben Davis, Blenheim Orange, Canada Baldwin, Esopus Spitzenburg, Fallawater, Fall Jenetting, Gano, Golden Russet (American), Hubbardson's Nonsuch, Jonathan, Keswick Codlin, King of Tompkins Co., McIntosh Red, McMahan White, Magog Red Streak, Maiden's Blush, Malinda, Mann, Newtown Pippin, Peach, Pewaukee, Pomme Grise, Primate, Princess Louise, Rhode Island Greening, Roxbury Russet, St. Lawrence, Salome, Stark, Swaar, Swayzie Pomme Grise, Wealthy, Winter St. Lawrence, Wolf River, Yellow Transparent, Ontario, Ribston Pippin, Colvert, Brockville Beauty.—42 varieties.

LATE GROUP.

Blue Pearmain, Cranberry Pippin, Grimes' Golden, Lawver, Northern Spy, Red Canada, Talman Sweet, Walbridge, Westfield Seek no Further, Yellow Bellflower.—10 varieties.

The following is a list of those who have recorded the blossoming dates of fruits during the past five years:—

Recorders of blossoming periods.

1. Theodore Tragé, Salt Spring Island, B.C.
2. Thos. G. Earl, Lytton, B.C.
3. W. B. Anderson, Comox, B.C.
4. Richard Layritz, near Victoria, B.C.
5. Henry Kipp, Chilliwack, B.C.
6. Tom Wilson, Vernon, B.C.
6a. T. A. Sharpe, Agassiz, B.C.
7. C. E. F., Ottawa.
8. Geo. E. Fisher, Freeman, Ont.
9. A. W. Peart, Freeman, Ont.
10. Richard Trotter, Owen Sound, Ont.
11. Thos. Beall, Lindsay, Ont.
12. E. B. Edwards, Peterborough, Ont.
13. G. Nicol, Cataraqui, Ont.
14. W. H. Pettit, Grimsby, Ont.
15. J. P. Cockburn, Gravenhurst, Ont.
16. E. Morden, Niagara South, Ont.
17. B. Gott, Strathroy, Ont.
18. G. C. Caston, Craighurst, Ont.
19. N. J. Clinton, Windsor, Ont.
20. Allen Bros., Winona, Ont.
21. Capt. Jas. Shepherd, Queenston, Ont.
22. Robt. Brodie, St. Henri de Montreal, Que.
23. Hon. S. Fisher, Knowlton, Que.
24. J. C. Chapais, St. Denis, Qe.
25. C. P. Newmann, Lachine Locks, Que.
26. Mrs. S. Foster, Knowlton, Que.
27. J. M. Fisk, Abbotsford, Que.
28. W. M. Pattison, Clarenceville, Que.
29. Asa Johnston, East Farnham, Que.
30. W. Hawker, St. John, N.B.
31. G. U. Hay, St. John, N.B.
32. A. H. Fairweather, Hampton, N.B.
33. W. W. Hubbard, Sussex, N.B.
34. C. E. Brown, Yarmouth, N.S.

LIST OF BEST VEGETABLES FOR FARMERS.

As all the experiments which are conducted with vegetables cannot be published every year on account of want of space; a list of the varieties of all the principal kinds which have proved the most satisfactory after several years tests was published in the report for 1898 under the heading "List of best Vegetables for Farmers." This gave in a concise form much valuable information as to the best varieties to plant and must have proved very helpful to those who studied it. As the annual reports are very liable to be mislaid during the year, and as one is apt to forget the name of a variety, it has been thought advisable to again publish this list with what changes another year's experience warrants making.

Asparagus.—Connover's Colossal is the best all round variety.

Beans.—Golden Wax or Wardwell's Kidney Wax, for early crop; Early Refugee, for medium; and Refugee or 1,000 to 1, for late crop, are the most satisfactory dwarf varieties. Southern Crease-back and Asparagus, (early) and Golden Andalusia, (late), are the best pole varieties.

Beets.—Egytian Turnip, Eclipse, and Bastian's Blood Turnip are three of the best varieties.

Borecole or Kale.—Dwarf Green Curled Scotch is the best.

Broccoli.—White Cape.

Brussels Sprouts.—Improved Dwarf is the most satisfactory.

Cabbage.—Early Jersey Wakefield (early), Succession (medium); Late Flat Dutch, Drumhead Savoy, (late), Red Dutch, (red), is a select list of the best varieties of cabbage.

Cauliflowers.—Extra Early Dwarf Erfurt and Early Snowball, (early); Kronk's Perfection, (medium) and Large Late Algiers are among the best.

Carrots.—Chantenay and Guerande or Oxheart are two of the best carrots, but if a good extra early sort is required the Early Scarlet Horn can be planted with advantage. It is a small variety.

Celery.—Golden Self-Blanching, Paris Golden Yellow, Improved White Plume, White Walnut (early); London Red, Perfection Heartwell, White Triumph, (late), are among the best.

Corn.—Early White Cory, Crosby's Early, Henderson's Metropolitan, (early); Perry's Hybrid, Stabler's Early, Early Evergreen (medium); Stowell's Evergreen, Country Gentleman (late.) In planting, the Country Gentleman should not be omitted, as it lengthens the season very considerably, and is of fine quality.

Cucumbers.—Peerless White Spine or White Spine, Cool and Crisp, and Giant Pera are three of the most satisfactory slicing varieties. Boston Pickling is a good pickling sort.

Egg Plants.—New York Improved and Long Purple succeed best.

Lettuce.—Black Seeded Simpson, New York, (curled), Tennis Ball, Salamander, and Golden Queen, (cabbage); Trianon and Paris White Cos lettuce make a good list.

Melons, Musk.—Long Island Beauty, Hackensack and Montreal Market, of the Nutmeg type, and Surprise, Bayview, Paul Rose and Christiana, of the other types, are all good.

Melons, Water.—Cole's Early, New Imperial, Ice Cream, and Phinney's Early, are early water melons of excellent quality.

Onions.—Yellow Globe Danvers, and Large Red Wethersfield, are two of the best onions in cultivation.

Parsnips.—Hollow Crown and Dobbie's Selected are both good sorts.

Parsley.—Double Curled is as good as any.

Peppers.—Cayenne, Cardinal, Squash, and Golden Dawn are four of the best.

Pease.—Gregory's Surprise, Gradus, Nott's Excelsior and American Wonder, (early); Heroine, Improved Stratagem, and McLean's Advancer, (medium). None of these are tall growing varieties. Juno (dwarf), Telephone, Veitch's Perfection (tall), (late).

Potatoes.—Extra Early: Early Ohio (pink), Earliest of all, Bovee and Burpee's Extra Early (pink and white). Early: Everett and Rochester Rose, (pink), Early Puritan, (white). Medium: Carman No. 1, (white), Empire State, (white). Late: Late Puritan (white), American Wonder (white), Rural Blush (pink).

Radishes.—Early: Rosy Gem, French Breakfast, Red Rocket. Late: White Strasburg, Long White Vienna. Winter: Long Black Spanish, Chinese Rose-coloured.

Rhubarb.—Linnæus and Victoria are the most satisfactory.

Salsify.—Long White is the best.

Spinach.—Victoria and Thick-leaved are the best.

Squash.—Early: White Bush Scalloped and Summer Crook Neck. Late: Hubbard.

Tomatoes.—Early: Conqueror, Dwarf Champion, Canada Victor and Early Ruby. Main crop: Brinton's Best, Livingston's Favorite, Matchless, and Baltimore Prize Taker.

There are many varieties of this vegetable which are almost equal in excellence and productiveness.

Turnips.—Early: Extra Early Milan and Red Top Strap Leaf. Swedes: Champion Purple Top, Skirvings Improved.

EXPERIMENTS WITH POTATOES.

The yields from the 143 varieties of potatoes grown for comparison in uniform test plots were very good this year, the best yielding variety, American Wonder, producing at the rate of 640 bush. 12 pounds per acre; while the poorest gave 204 bush. 36 pounds per acre. The average yield per acre from the 143 varieties was 410 bush. 47 pounds, which is 291 bush. 47 pounds more than the average for Ontario this year, the average for Ontario being 119 bush. Had these varieties been grown in acre plots, the yields would not have been so large, but considering the fact that the poorest variety of the 143 tested, yielded 85 bush. 36 pounds more than the average for Ontario, it seems remarkable that larger crops are not produced throughout the country. The soil in which the potatoes were grown was a sandy loam, and, while in a good state of cultivation, it was not what would be called rich, although it was given a good dressing of barnyard manure in the spring of 1898. A crop of tobacco was taken off the same land in 1898. The soil was ploughed in the autumn of 1898, and again in the spring of 1899, when it was also disc harrowed and harrowed twice with the smoothing harrow before planting. The drills were made about 6 inches deep and 2½ feet apart, and the sets, which had at least three eyes, were of good size and were dropped 1 foot apart, each variety occupying one row 66 feet long. The potatoes were covered with the hand hoe to insure the most uniform conditions. The potatoes were cultivated when required throughout the summer, but were not hilled up. They were sprayed with Paris green and Bordeaux mixture to destroy the potato beetle and prevent blight. The potatoes were planted on May 22, and 23, and were dug on October 5, 6 and 7. There was no scab or rot this year.

For many years, experimenters, both in Europe and America, have given the potato much attention, but the results obtained by them have, in many cases, been very different. Varieties of potatoes differ so much in their season, habit of growth, manner of producing their crop, number and vigour of the eyes on the tubers, and other characteristics, that one variety may give one result if the sets are cut or planted in a certain way, while another may give another result. However, there are certain general principles which have been established by the work which has been done.

The following experiments include some of the most popular of those tried by experimenters, and while the results obtained are by no means conclusive, they may lead others to try experiments with their own varieties.

Potatoes—Planting at Different Distances Apart.

During the past four years an experiment has been tried in planting the sets at different distances apart in the rows; the rows in each case being 2½ feet apart. The best results have been obtained so far by planting the sets 12 inches apart, although it will require several years before accurate conclusions can be drawn. There was very little difference in the proportion of marketable and unmarketable tubers in this experiment.

Distance apart of Sets.	Seed required per acre.		Yield per acre, 1896.		Yield per acre, 1897.		Yield per acre, 1898.		Yield per acre, 1899.		Average yield per acre, 4 years.		Average yield per acre after deducting seed.

Potatoes—Planting at Different Depths.

An experiment has been conducted during the past two years in planting potatoes at different depths in rows 2½ feet apart and 12 inches apart in the rows. Each set had at least three eyes. The soil was sandy loam, both years. Level cultivation was adopted, and thus very little soil was thrown on the potatoes after they were covered at the time of planting. The following table shows that the best yields were obtained from planting the sets only 1 inch deep. As the relative yields from the different depths of planting have not been the same in both years, it will be necessary to continue this test for some time before accurate conclusions can be drawn. Notes were taken on the depths at which tubers were formed, and it was found that most of them were within 4 inches of the surface of the soil, even where the set had been planted 6, 7 and 8 inches deep. Where the sets were planted less than 4 inches deep nearly all the tubers were formed between that and the surface of the soil.

Depth of Planting.	Yield per acre, 1898.		Yield per acre, 1899.		Average yield per acre, 1898-9.

POTATOES—PLANTING AT DIFFERENT DATES.

In 1898 an experiment was begun in planting potatoes at different dates, beginning when the main crop was put in and continuing at intervals of two weeks until August 23, 1898 and July 23, 1899. An early and a late variety were used in each case. Early Norther (early) and Irish Daisy (late) in 1898, and Early Norther and Rural Blush in 1899. It will be seen that there was a regular decrease in the yield from each planting.

NOTE.—The yield from the third planting in 1898 was not divided into marketable and unmarketable, hence an average cannot be made of them for that planting.

EXPERIMENTS WITH TOMATOES.

This year 144 varieties were grown for comparison. As lack of space would not permit of a table being published of all the varieties tested, only twenty-five of the best yielding sorts, with data regarding the yields from early and late pickings, are given. In addition to these, are tables in which may be found the names of the six wrinkled varieties which have given the best average yields of ripe fruit during the past four years, and also twelve of the best yielding smooth varieties for the same time.

The seeds were sown this year in hot beds on March 29; the young plants pricked out into strawberry boxes on April 28, and planted in the open ground on June 6, 4 feet apart each way, five plants of each variety being used. The soil was a light sandy loam, which had not received any fertilizers since 1897. The plants grew well, not one having to be replaced. The soil was kept cultivated with the horse cultivator and hoed until the plants became too large to permit of further hoeing.

The season was unfavourable for ripening a heavy crop of tomatoes, and the yields were much less than last year.

TWENTY-FIVE BEST YIELDING VARIETIES OF TOMATOES, 1899.

Variety.	Seedsman.	Date of First Ripe Fruit.		Yield of Ripe Fruit. — First three pickings		Yield of Ripe Fruit. — Last three pickings		Total Yield of Ripe Fruit. — All pickings		Remarks.

Atlantic Prize	" 3	14	10	Medium size, regular, smooth, scarlet.
Bond's Early Minnesota	July 30	14	7	Medium size, regular, smooth, purple.
Horsford's Prelude	Aug. 2	14	7	Small, regular, smooth, scarlet.
Mayflower	" 3	14	5	Large, regular, smooth, scarlet.
Essex Hybrid	" 2	14		Medium size, regular, smooth, purple.
Livingston's Favourite	" 11	13	8	Large, regular, smooth, scarlet.

Of the twelve best smooth varieties, Brinton's Best, Baltimore Prize Taker and Livingston's Favourite are the best for a main crop, but others have the advantage of earliness and should be planted where early tomatoes are desired.

CELERY—TEST OF VARIETIES.

Experiments were conducted this year with forty varieties of celery, nearly all of which were grown in duplicate. The soil was a good sandy loam which retained the moisture very well throughout the season. The land was prepared by ploughing it about 8 inches deep and then harrowing it into good tilth with a smoothing harrow. Drills were made with a drill plough from 10 to 12 inches deep, and 4 feet apart. Well rotted barn-yard manure was then put in the drills to a depth of about 3 inches and thoroughly incorporated with the soil by means of a digging fork. The soil was now ready for the plants. The celery seed was sown in hot-beds on April 5, and the young plants transplanted to a cold frame on May 26. They were planted out 8 inches apart in the drills, which were now almost level with the rest of the ground, on July 12. The soil was hoed on August 15, and on the 30th the soil was cultivated and the plants packed by hand and hilled up with the hoe. The soil was again cultivated on September 16, and the plants packed by hand and finally hilled up with the spade. During the growing season the foliage was kept covered with Bordeaux mixture, and there was very little disease, although other celery in the neighbourhood of Ottawa suffered. The celery was dug on October 20.

The blanching of early varieties by means of boards gives very satisfactory results, and this method is being more generally adopted by growers. The later kinds are kept best while bleaching, and before being sold, by standing the plants close together in a cool, dark place on moist sand, or by burying the roots in the sand. To have it keep well, the tops should be kept dry and the roots moist.

In the following table a list is given of the varieties which have been tested during the past two years, with notes on their yields, season and quality :—

Name of Variety.	Seedsman.	Yield from 24 plants, 1898.	Yield from 30 plants, 1899.	Yield from 30 plants. 1899.	Total yield from 104 plants. 1898-9.	Remarks.

EXPERIMENTS WITH CORN.

During the past two years a large number of varieties of sweet corn have been tested, in order to determine their relative standing as regards time of being ready for use, quality, size of ear, yield and height of plant, and in the following table particulars will be found regarding these points. In 1898, thirty-six varieties were tested, and in 1899, seventy-six varieties. The soil in which the corn was grown in 1899 was sandy loam. Clover was ploughed under in the spring, the land disc-harrowed and harrowed twice with the smoothing harrow. The corn was planted on May 30 in hills three feet apart each way, about six kernels being planted in each hill. After the seed had germinated and there was no longer danger from cut worms, the number of plants in a hill was reduced to four. Twelve hills of each variety were used for comparison. The corn was kept thoroughly cultivated during the summer, and when growth had ceased in the autumn it was cut and the ears removed and counted.

Of the varieties tested in 1899, the following were the most promising, given in the order in which they were ready for market :—

EARLY.—Extra Early Beverly (not a very sweet corn but the earliest yet tested), Extra Early Cory, Early Marblehead, Lackey's Early Sweet, Burpee's Earliest Sheffield (not a very sweet variety, but productive and with uniform ears), First of All (Pearce), Henderson's Metropolitan.

SECOND EARLY.—Crosby's Extra Early, Early Market, Early Giant Sweet, Low's Perfection, Child's Honey Dew, Boston Market.

INTERMEDIATE.—Black Mexican, Stabler's Early, Perry's Hybrid, New Early Evergreen, New Honey Sweet, Guarantee Sweet.

LATE.—Ne Plus Ultra, Country Gentleman.

TOBACCO.

This year forty-eight varieties of tobacco were grown for comparison as to time of ripening and productiveness ; notes were also taken on other characteristics regarding them. The seed was sown in a hot bed on April 4, the young plants transplanted into a cold frame on May 20, and planted in the field on June 15. The soil where the tobacco was grown was a light sandy loam, which received a dressing of well rotted barnyard manure at the rate of twenty tons per acre before it was ploughed in the spring of 1899. The soil was ploughed on June 7, disc harrowed once, and harrowed twice with the smoothing harrow before planting. The plants were set 3 by 3½ feet apart, the land being previously marked with a corn marker, and the plants set at the intersections of the marks. Fifteen plants of each variety were used. The soil was cultivated frequently, four times in all, until the plants were too large to admit of the passage of a horse between the rows without injury to the leaves. The plantation was hoed twice in order to kill the weeds not destroyed by the cultivator, and to loosen the soil close to the plants. The tobacco was cut on September 13, and taken to the curing house where, after it was cured, the plants were stripped and the weights of the leaves taken.

The season was not very favourable to tobacco, the weather being cool or wet at the time when it should have been hot. The yields, however, from the different varieties, were large. It must be pointed out, however, that it would be difficult to obtain such yields on large areas.

In the following table particulars are given of the date of topping, total weight of first grade dry leaves, weight of second grade dry leaves, weight of third grade dry leaves, estimated total weight per acre of dried leaves, and stage of maturity at time of cutting :—

TOBACCO—TEST OF VARIETIES.

Name of Variety.	Seedsman.	Date of Topping.	Yield per acre, 1st grade dry leaves.	Yield per acre, 2nd grade dry leaves.	Yield per acre, 3rd grade dry leaves.	Total yield per acre, dry leaves.	Condition of leaves when cut.

In addition to the varieties grown in small plots, three kinds, White Burley, Havana Seed Leaf, and Little Oronoka, were grown on a larger scale, one and one-half acres in all being devoted to these varieties. Part of the land was manured at the rate of 20 tons per acre with well rotted barnyard manure, and otherwise received the same treatment as described for the smaller plots.

As the seed was not received until late, the plants were not set out until June 27, which was not as early as desirable, and on this account the Havana Seed Leaf and Little Oronoka were not as far advanced at the time of cutting as they should have been. The yield of White Burley was also much reduced on this account. The proportion of third grade is large owing to sand blowing and injuring the leaves badly.

The tobacco was cut on September 13 and 14, and taken to the new curing house, where the plants were hung on laths and cured, after which the leaves were stripped off and made into hands, and the tobacco is now ready for fermentation.

The following table gives the results obtained from the three varieties tested :—

TOBACCO—LARGER PLOTS.

FOREST BELTS.

In the Report for 1897 a table was published giving the measurements of trees in the forest belts at the Central Experimental Farm. This table is again published this year with the additional measurements which have been taken in the meantime.

In addition to the measurements hitherto taken, the diameter of the trees at a height of 4 feet 6 inches from the ground was recorded this year. It is intended that the measurement taken at this height will take the place of that, one foot from the ground, as it will be more valuable. As many who now receive the Annual Report did not do so in 1897, it has been thought wise to repeat the matter published that year, in which the forest belts are described and the objects for which they were planted, explained, making such changes as are necessary after the two years which have elapsed since then.

The forest belts at the Central Experimental Farm extend along its northern and western boundaries; the belt on the western boundary is 165 feet wide, and that on the northern boundary, 65 feet; their total length being nearly 1¾ miles. The number of trees growing in these belts, including those in an evergreen clump, is about 20,500. The objects, for which these forest belts were planted, are well expressed in the report of the Director for 1893 as follows :—

"There were several objects in view in planting the belts of forest trees which line the west and north sides of the farm. One was to test by actual experiment with a number of different species, the comparative results in growth and development to be had by planting at different distances apart. Five feet by five, five feet by ten and ten feet by ten were the distances chosen for these tests. Another question on which information was desired was the relative growth to which trees would attain when planted

in blocks of single species as compared with those planted in mixed clumps where they are associated with a number of other sorts. Further information was sought as to how far the crops on the farm located near these tree belts will be influenced by the shelter they would afford as growth progressed. In the planting, the grouping was also designed with the object of producing pleasing effects on the landscape by the intermingling and blending of varieties. The main purpose, however, was to get all the useful data possible with regard to the more important timber trees of economic value so that object lessons in tree growth might be available to any who in future might desire to study this subject or to engage in the enterprise of timber growing."

Although it is but eleven years since the first trees were planted in the belts referred to, the growth already made is a useful object lesson and should encourage the more extensive planting of timber trees. The soil in which the trees were planted was in many instances poor, and while a number of species appear to succeed almost as well on poor as on good land, yet some kinds require good soil in order to grow them successfully. As to the distance apart at which it is desirable that trees should be planted, those which were put five by five feet apart are making, in most cases, the best trees for timber purposes, as the lower limbs are dying, leaving the trunks clean which will make the wood freer from knots than where planted ten by ten, or ten by five feet apart, as at those distances there are, as yet, few instances where the lower limbs have died. The trees planted five by five feet apart, also, make more growth in height than where wider planting was adopted, but the diameter of the trunk is not so great. The closely planted trees are more protected from storms and there are fewer broken tops and crooked stems. The desirability of close planting was also very apparent until quite recently in the condition of the surface of the ground where the trees are ten feet apart, which, in a number of cases, still required cultivation although the trees had been planted for eight years ; as it was necessary, in order to keep sod from forming and checking the growth of the trees, to cultivate the soil, whereas, in most instances, where the trees are planted five by five feet apart, the surface soil was kept shaded and moist, and sod did not form. As the conditions of soil are different in the belts where the trees are planted in clumps of a single species and where the several kinds are mixed together, a fair comparison of these two methods of planting cannot yet be made, but the advantages derived from mixing the leafier sorts of trees with those which are not very leafy, are already apparent. Where thin foliaged trees had been planted five by five feet apart and had had eight years' growth, the sod still formed very readily unless the soil was kept cultivated, thus showing that sufficient shade was not afforded to prevent the growth of grass and weeds.

None of the trees in the forest belts were cultivated in 1899.

Owing to the unsuitability of soil and climate, the following kinds of trees have not succeeded in the forest belts along the Western boundary, and in consequence most of them were removed this autumn and part of the land replanted with other species :

Species removed :—Red Maple, Norway Maple, European Mountain Ash, Buttonwood, Horse Chestnut, Kentucky Coffee Tree.

TREES PLANTED IN THE FOREST BELTS IN 1899 :—As the experience of the past eleven years had proven that in many cases trees planted 5 by 5 feet apart had required a great amount of cultivation, in order to give them favourable conditions for making good growth, and in consequence had proven rather expensive, it was decided, when replanting the vacant places this year, to plant the trees closer together. The method adopted was to plant both trees and shrubs, the latter, which were in the majority, being used for the purpose of getting the ground shaded in as short a time as possible, so that weeds would be smothered, moisture conserved, and the soil kept from baking, which would obviate the necessity of cultivating.

Two blocks of trees were planted, in one of which the following species were planted for permanent trees :—White Pine, 10 by 12 feet apart ; Hard Maple, 10 by 12 feet apart. Spaces have been left in this block for White Ash, which when planted in the spring of 1900 will be 10 by 5 feet apart. The remainder of the block is made up of

Box Elder, Rosemary Willow (Salix rosmarinifolia), Ninebark (Neillia opulifolia) and Alder buckthorn (Rhamnus Frangula), all of which were planted for the purpose of filling in the spaces between the permanent trees. When all the trees in this block are planted every tree and shrub will be just 2½ feet apart each way.

In the other block, the following trees have been used as permanent trees :—Black Walnut, 10 by 10 feet apart ; Hard Maple, 10 by 10 feet apart ; and European Larch, 10 by 10 feet apart, while Box Elder, Sand Cherry and Alder Buckthorn have been used for filling in.

The total number of trees and shrubs planted, with height of same, was :—

Name.	Number planted.	Height when planted.
White Pine *(Pinus Strobus)*	186	9 to 12 inches.
Black Walnut *(Juglans nigra)*	137	3 ft. (2 yrs. old.)
Hard Maple *(Acer saccharinum)*	304	18 to 24 inches.
European Larch *(Larix europæa)*	99	8 "
Box Elder *(Acer Negundo)*	918	4 to 6 "
Ninebark *(Neillia opulifolia)*	461	4 to 6 "
Sand Cherry *(Prunus pumila)*	420	4 "
Alder Buckthorn *(Rhamnus Frangula)*	480	4 to 6 "
Norway Spruce *(Picea excelsa)*	75	12 to 15 "
Rosemary Willow *(Salix rosmarinifolia)*	1819	unrooted cuttings.
Total	4899

In the above table the average growth is given of most of the important timber trees growing in the measurements of average trees, and give a fairly accurate idea of the growth these make each year. Until many of them began to spread so much that it was difficult to determine the leader, hence the total height where the main branches are very divergent, or the extremities pendulous, the total height is given as less

at the Central Experimental Farm.

forest belts at the Central Experimental Farm. The figures published are the average results from the 1897, and in some cases until 1898, the annual growth was taken in measuring the trees, but the crowns of is now taken. This change has lessened the apparent annual growth for those years, and in some cases, than that of the year previous.

ARBORETUM.

Although last winter was severe, and comparatively little snow fell until March, the number of trees and shrubs which were winter-killed was little, if any, above the average. The genus *Prunus* suffered, perhaps, more than any other in this regard: the reason probably being that many of the varieties were grafted on tender stocks, as most of the losses occurred from root-killing. Notwithstanding the losses, however, which occur every winter, the collection is getting larger each year.

This year a catalogue was published of the trees and shrubs which have been tested up to this time, and the introductory matter from that catalogue, which is herewith quoted, will give some idea of the progress which has been made since 1889, when the first planting was begun:—

"When the Central Experimental Farm was established at Ottawa, in 1886, it was decided that a portion of the land purchased, consisting of sixty-five acres out of a total of four hundred and sixty-five, should be devoted to the purposes of an Arboretum and Botanic Garden, where trees, shrubs and plants from all parts of the world could be brought together and tested as to their hardiness and adaptability to this climate.

"Work was begun on the Experimental Farm in the spring of 1887, but the first planting in the Arboretum and Botanic Garden was not done until the autumn of 1889. During that season 200 species of trees and shrubs were planted, two specimens of each, grouped in their natural orders. In planting these they were placed at such distances from each other as was thought would be sufficient to permit of the full growth and development of the individual specimens. Many additions were made from year to year, and in 1894 the collection contained about 600 species and varieties. Up to that time this part of the work had been in charge of Dr. James Fletcher, Botanist and Entomologist of the Dominion Experimental Farms, under whose care great progress had been made. In the spring of 1895, at the request of Dr Fletcher, a change was made, and the Botanic Garden and Arboretum was placed in charge of Mr. W. T. Macoun, who was then the Director's Assistant and Foreman of Forestry. In the spring of 1898 Mr. Macoun was appointed Horticulturist of the Central Experimental Farm and Curator of the Arboretum and Botanic Garden, and under his energetic management, aided by such advice and oversight as the Director has been able to give, this collection has been rapidly increased. The total number of species and varieties which have been, or are now, under test, all of which are referred to in the accompanying catalogue, is 3,071. Of these, 1,465 have been found hardy, 330 half hardy, 229 tender, 307 have been winter-killed, and 740 have not been planted long enough to admit of an opinion being given as to their hardiness. Where they have been tested one or more winters an opinion has been expressed on this point based on the experience had. Those which have passed through one or more winters uninjured, or with very slight injury to the tips only of the branches, have been pronounced hardy; where the new wood has been killed back from one-fourth to one half its growth, such are said to be half hardy, and those which have had their wood killed in winter to the snow line or to the ground have been noted as tender. Where the experience of one winter only has been had, the conclusions reached can only be regarded as tentative, and may require modification in future.

"In the catalogue the botanical names of the trees and shrubs are arranged alphabetically, and where a species or variety has a common name this also is given. The countries are named of which the trees and shrubs are native, also the year in which they were planted. In compiling this work the nomenclature and classification of the "Index Kewensis" and the "Kew Guide" have been adopted. The name of the species or variety is printed in bold faced type, followed by the author's name in small capitals. The term *Hort.* indicates a garden or gardener's variety. Synonyms of the genera and species are printed in italics. The common names given are those found in the leading botanical works of modern authors.

"While a large number of synonyms have been recorded, it is probable that there are still included in this catalogue some which are listed as species or varieties which are really synonyms. In recording the synonyms the names given are only those under

which the species or varieties have been received at the Experimental Farm and do not include all the known synonyms in each case. There has not yet been time to carefully identify every species and variety under test, and it is quite probable that there may be some among them wrongly named. Any botanists who are making a special study of any family or genus would confer a great favour on the authors if they would kindly note any apparent inaccuracies and report them, so that such errors may be rectified.

"The Arboretum at the Central Experimental Farm is now much visited and an increasing interest manifested in the progress of the work by botanists as well as by the general public. It is hoped that this catalogue will be useful to visitors as a hand-book and that its distribution among botanists and others specially interested in the growth of trees and shrubs in this country and abroad will convey much information as to the relative hardiness of species in this part of Canada and at the same time give correct ideas as to the character of the climate in this part of the Dominion."

PROGRESS OF THE WORK.

Little change has been made in the routine work in connection with the Arboretum and Botanic Garden during the past year. The grass is kept cut with a pony lawn mower; circles are kept without grass about each specimen and the surface soil within these kept loose with a hoe; notes are taken of the hardiness, growth and time of blooming of the trees and shrubs, and they are also kept well labelled. An addition of 200 specimens was made to the herbarium of the Arboretum and Botanic Garden, which was begun last year, making a total of 735 species and varieties.

An area of about two acres was seeded down to lawn grass this year, which will improve the appearance of that part of the Arboretum very much. Several acres which had hitherto been in sod were ploughed up this year and planted with Indian corn. After the crop was removed the land was again ploughed, and this will be in good condition for planting next year.

A new label has been adopted for the trees, shrubs and plants, which will prove much cheaper and more serviceable than the enamelled labels hitherto used, and is much more useful than the small zinc labels, which were rat er difficult to read. They are 3 by 6 inches, made of galvanized iron, painted white, and are supported by heavy wire bent to form two legs and soldered to the back of the label. The common and the scientific name of the plant and the country of which it is a native, are painted in black letters on each label.

SOME GOOD LOW-GROWING FLOWERING SHRUBS.

It very frequently happens that one's grounds will not permit of having many large shrubs or trees, and a list of some of the best low-growing shrubs of compact habit should prove useful to those who are thus situated. The following shrubs cover a blooming period from early spring until autumn, and with the addition of some good perennials would make a small place very attractive. Although some of the kinds mentioned are not perfectly hardy as far as their wood is concerned, they nearly always produce a fine display of blossoms. Most of them are so low-growing that they are covered with snow nearly every winter and are thus well protected.

In my Report for 1897 a list was published of 100 of the best ornamental trees and shrubs, and the following list may be used as a supplement to that one by those having large grounds:

Berberis Aquifolium:—Oregon Grape: British Columbia. Height, 1 to 2 feet. In bloom third week of May. Flowers bright lemon-yellow. Leaves evergreen, smooth and shiny assuming attractive shades in autumn.

Calluna vulgaris.—Heather: Northern and Central Europe. Height 1 to 3 feet. Bloom July and August. This is too well known for description. In the protection

of an evergreen hedge where the snow covers it in the winter, this pretty little shrub is succeeding admirably.

Caragana grandiflora.—Large flowered Caragana: Caucasus. Height 4 feet. In bloom third week of May. Flowers large, bright yellow, pea-shaped. Very pretty when in full bloom. This somewhat resembles *C. frutescens*, but has larger flowers.

Cassandra calyculata.—Leather Leaf: Canada: United States, Height 1 to 3 feet. Blooms in June. Flowers pure white in terminal racemes. This pretty native shrub has succeeded well here, planted in moist soil.

Ceanothus americanus Marie Simon: Height 2 feet. Begins to bloom in third week of June. Flowers small, pale pink, borne in clusters. This is a profuse bloomer and is very pretty when at its best. It kills back when under the protection of an evergreen hedge, but always is a mass of bloom in summer.

Clethra alnifolia.—Sweet Pepper Bush: United States. Height 3 to 4 feet. In bloom first week of August. Flowers small, white, in long clusters. Almost hardy. This is not a very attractive shrub, but it flowers at a time when few trees or shrubs are in bloom and is, therefore, desirable.

Cytisus hirsutus.—Europe: Height 1 foot. In bloom first week of June. The flowers of this little shrub are bright yellow and pea-shaped. It is quite attractive when in full bloom. Although not perfectly hardy, a good show of bloom is always assured.

Cytisus purpureus.—European Alps: Height 6 to 12 inches. In bloom fourth week of May. Flowers pea-shaped, bright purple, and borne in the axils of the leaves along the branches. One of the prettiest dwarf shrubs tested here and almost hardy.

Daphne Cneorum.—Garland flower: Eastern Europe. Height 1 to 1½ feet. In bloom second week of May. Flowers bright pink, and sweet scented. A very pretty little evergreen, quite suitable for flower borders. It blooms a second time in autumn.

Daphne Mezereum—Common Mezereon: Europe. Height 3 to 4 feet. Blooms early in May. Flowers red, very sweet scented. This is a well known early flowering shrub. It is not quite hardy at Ottawa, but if given some protection it will bloom very well.

Deutzia gracilis.—Japan Snow-flower: Japan. Height 12 to 18 inches. In bloom first week of June. Flowers white, borne profusely in terminal clusters. It is unfortunate that this attractive little shrub is not hardier. Some seasons it is covered with bloom, while again after a very severe winter there is very little. The wood kills back usually to near the ground. It is much used by florists for forcing.

Diervilla Florida (rosea) nana foliis variegatis.—Dwarf Variegated Weigelia: Japan. Height 1 to 2 feet. In bloom first week of June. The flowers are of a delicate shade of pink and the leaves well variegated with green and yellow. Not altogether hardy, but if planted where the snow will cover it well or where it may be artificially protected, it will succeed well.

Genista tinctoria.—Dyer's Greenweed. Europe. Height 1 to 2 feet. Begins to bloom in fourth week of June. Flowers bright yellow, pea-shaped. A very pretty little shrub, continuing in bloom for some time. There is a double-flowered variety, which is also good.

Hedysarum multijugum.—South Mongolia. Height 2 to 5 feet. In bloom 4th. week of June. Flowers bright pink, pea-shaped, borne in racemes. This shrub is of

graceful habit and has attractive foliage, and is a striking object when in full bloom. It is not, however, perfectly hardy.

Hypericum kalmianum.—Kalm's St. John's Wort: Ontario. Height 2 to 4 feet. Begins to bloom second week of July. Flowers large, bright yellow. A very ornamental shrub, continuing in flower until late in the summer.

Jamesia americana.—Rocky Mountains. Height 1 to 2 feet. In bloom 2nd week of June. Flowers white in terminal heads. This is quite a pretty little shrub and when not in bloom the leaves, which have a silvery appearance, make it still ornamental

Lespedeza Sieboldii.—(*Desmodium penduliflorum*). Japan. Height 4 feet. Blooms in September. Although this shrub is killed to the ground every winter, there is usually a profusion of bright purplish-red, pea-shaped blossoms, which are borne on large spikes. This is a very fine autumn flowering shrub.

Lonicera Alberti.—Albert Regel's Honeysuckle. Turkestan. Height 2 to 4 feet. In bloom 4th week of May. Flowers bright pink. This beautiful little honeysuckle with its sweet-scented flowers, pendulous branches, and narrow leaves, is one of the most hardy and desirable shrubs.

Potentilla fruticosa.—Shrubby Cinque-foil, Canada. Height 2 to 4 feet. In bloom 2nd week of June. Flowers large, bright yellow. An attractive shrub when in bloom.

Pyrus (Cydonia) Maulei.—Maule's Japanese Quince. Japan. Height 1 to 3 feet. In bloom 2nd week of May. Flowers bright red. The flowers of this little shrub are very ornamental, and in the autumn, when the golden coloured, highly perfumed quinces are ripe, it makes a very interesting object. It is much hardier than *P. japonica*, of which some authorities call it a variety.

Rhododendron viscosum.—White Swamp Honeysuckle. United States. Height 2 to 4 feet. Blooms in latter part of June. Flowers white, tinged with pink, sweet scented, with a sticky substance on the tubes of the corollas. This is really an Azalea, though now included with the Rhododendrons. It is one of the few hardy species of this genus, and makes an attractive shrub when in full bloom.

Spiræa arguta.—Europe. Height 3 to 4 feet. In bloom 3rd week of May. Flowers pure white, produced very profusely in compact clusters. This is the earliest flowering spiræa grown here, and is one of the best hardy shrubs of recent introduction. It is a graceful little spiræa with pendulous branches, but its chief beauty lies in the abundance of its pure-white flowers.

Spiræa japonica alba (S. callosa alba).—White-flowered Japanese Spiræa. Japan. Height 1 foot. In bloom 2nd week of July. Flowers white in flat heads. This is a neat little shrub, and although not altogether hardy, blooms profusely every year.

Spiræa japonica Bumalda Anthony Waterer.—Europe. Height 1 foot. Begins to bloom 1st week of July and continues in flower for a long time. Flowers bright, purplish-red, borne in compact heads. This is one of the prettiest dwarf shrubs yet tested at Ottawa.

Zanthorrhiza apiifolia.—Parsley-leaved Yellow-root. United States. Height 1 to 2 feet. In bloom 1st week of May. Flowers dark, brownish-purple. It is pleasant to meet this little shrub in early spring with its peculiar, almost chocolate-coloured flowers, and it makes an interesting and pretty object at that time of the year.

AN ADDITIONAL LIST OF GOOD PERENNIALS.

In my report for 1897 a list was published of 100 of the best perennials tested here, and there is reason to believe that it has proven very useful to persons who were desirous of planting some good varieties of perennial plants. In 1898, short descriptions were published of twelve more good sorts, and this year the following species and varieties are added, all of which are well worth planting :—

Cimicifuga racemosa.—Snakeroot. North America. Height 5 to 6 feet. Blooms during 2nd week of July. Flowers small, pure white, on very long spikes. Owing to its great height and striking appearance when in bloom, this is very desirable for the rear of the border.

Epimedium macranthum.—Large-flowered Barren-Wort. Japan. Height 12 to 15 inches. Blooms during 2nd week of May. Flowers white, borne on racemes having from six to ten flowers. A very graceful and pretty plant, the leaves of which are also ornamental. There are several fine varieties of this species, the commonest, perhaps, being *violaceum* with large lilac purple flowers. All the barren-worts are beautiful and this is one of the best.

Euphorbia corollata.—Flowering Spurge. United States. Height 18 inches. Begins to bloom the 1st week of July and continues until autumn. Flowers small, pure white, with a greenish centre, borne profusely on broad umbels. This is a very graceful plant and the flowers should prove excellent for cutting.

Gypsophila Stevenii.—Steven's Chalk Plant. Caucasus. Height 1 to 2 feet. Begins to bloom in the latter part of June. Flowers small, white, numerous, on loose panicles. A little earlier than *G. paniculata* and with larger flowers.

Linum flavum.—Yellow-flowered Perennial Flax. South Europe. Height 12 inches. Begins to bloom during the 3rd week of June and continues all summer. Flowers, medium size, bright golden yellow, produced in abundance on branching heads. On account of the long season during which this plant is in bloom, the profusion of flowers and their attractive appearance, it is a very desirable perennial.

Lupinus polyphyllus.—Many-leaved Lupine. North-west America. Height 3 to 4 feet. Begins to bloom in 1st week of June. This is a fine, showy, stately plant with long spikes covered with deep blue pea-shaped flowers. There are several good varieties including a white one.

Lysimachia Nummularia.—Creeping Jenny; Moneywort. Europe. Creeping. Begins to bloom in the 3rd week of June and continues throughout the remainder of the summer. Flowers deep yellow. This is a pretty little plant, spreading rapidly and succeeding admirably in shady places.

Lythrum Salicaria.—Common Purple Loosestrife. Europe. Height 4 feet. Begins to bloom in July and remains in flower a long time. Flowers small, bright reddish-purple, borne on long branching spikes. As the flowers of a spike are not all open at the same time, the blooming period is much lengthened. It makes a good show in the rear of the border. There is a fine variety *superbum* with rose-coloured flowers.

Malva moschata alba.—White-flowered Musk Mallow. Europe. Height 2 feet. Begins to bloom in the 3rd week of June and continues for some time. Flowers large, pure white, borne in terminal and axillary clusters. A very showy perennial.

Petalostemon violaceus.—Prairie Clover. Prairies of Canada and United States. Height 1 foot. Begins to bloom during 1st week of July. Flowers small, bright

purplish-pink, borne on short heads. This is a very attractive little plant which continues to bloom for a long time and is quite desirable for the front of the border.

Salvia azurea grandiflora.—(S. Pitcheri) Large Blue-flowered Sage. Texas. Height 4 feet. Blooms in September. Flowers are of a lovely shade of blue, borne on long spikes. This is one of the finest autumn flowering perennials.

Yucca filamentosa.—Adam's Needle; Ghost Plant. East Virginia and Southward. In bloom 2nd week of July. Height 4 to 5 feet when in bloom. Plant 12 to 18 inches high. When not in bloom this is a rather stiff, stemless, evergreen plant with broad leaves on the margins of which are white thread-like filaments. When the flower spike appears the plant assumes a different appearance as the spike shoots up to a height of four feet or more, bearing a large number of drooping bell-shaped flowers which are white with a greenish tinge. It now becomes a very striking and beautiful object. It has proven perfectly hardy here without artificial protection.

REPORT OF THE CHEMIST.

(Frank T. Shutt, M.A., F.I.C., F.C.S., F.R.S.C.)

Dr. Wm. Saunders,
Director, Dominion Experimental Farms,
Ottawa.

Ottawa, Dec. 1, 1899.

Sir,—I have the honour to submit herewith the thirteenth annual report of the Chemical Division of the Experimental Farms.

The matters that receive attention therein may be briefly referred to as follows:—

Soils.—The analytical data obtained on a representative sample of soil from certain flooded lands in the Dauphin district, Manitoba, are given. Comparing them with those from soils of the Red River Valley, published by us some few years ago, certain differences are to be noted, the chief of which is the smaller percentage of clay. In all the essential elements, this Dauphin soil is considerably above the average, and quite free from sourness and alkali. With drainage and proper culture it would no doubt prove a very fertile soil.

An instructive example of an impoverished soil was also submitted to analysis. We place side by side the results of its analysis with those obtained from a sample of virgin soil, collected in the vicinity of the field that had been cultivated for many years without any adequate return of plant food. The study of these data will prove of more than ordinary interest to all those possessing partially exhausted soils.

Since it would be impossible, and perhaps undesirable, to insert in this report all the analytical figures resulting from the examination of soils sent in by farmers during the past year, a general account or summary of our conclusions has been written. This not only points out wherein soils of reduced productiveness are deficient, but indicates rational and economical means that can be adopted for their improvement. It should prove a valuable contribution to the literature of this very important question, which is one of wide interest throughout many districts of eastern Canada.

Naturally-occurring Fertilizers.—First in importance of these is the investigation into the merits as a fertilizer of marsh mud—a tidal deposit from the Bay of Fundy.

We determined not only the total amount of plant food present—which is by no means large—but also the proportion of such which is, comparatively speaking, ready for immediate crop use. It has been demonstrated that this proportion is much larger than in ordinary fertile soils (to which in many respects these deposits are similar) and thus we have an explanation for the experience of many farmers who have found an immediate but not a lasting benefit from an application of such substances. To obtain the best returns from the use of marsh mud, organic matter and nitrogen—either as barn-yard manure or as a green crop of clover turned under—must also be furnished. In many instances, the value of these tidal deposits as fertilizers would be increased by a slight dressing of lime.

The interest in swamp muck as a cheap source of humus and nitrogen is apparent from the number of samples sent in for analysis. Of these, nineteen have been submitted to chemical examination and are here reported on.

Other fertilizers that have received attention comprise wood ashes, ashes from a tannery, fish pomace and sludge from the purification of sewage.

Foods and Feeding Stuffs.—We are continuing our investigation as to the relative merits of Canadian grown grasses. It may be possible during the coming year to issue a bulletin on this subject, supplementing the one (No. 19) already published.

In the present report are to be found accounts of the following fodders: Broadleaf hay from New Brunswick, Hay extract, Cotton seed meal, and the seed of 'Lamb's Quarters.' The latter is, unfortunately, a prevalent weed in many parts of the North-west, and the seed, obtained in comparatively speaking large quantities from the thresher, has been employed, after grinding or boiling, as a feeding stuff.

Chemistry of Insecticides and Fungicides.—Several questions relating to materials used in spraying mixtures have been referred to us during the past year. Certain investigations in connection therewith were accordingly undertaken, and since the results will be of interest to fruit growers and orchardists, they are here recorded.

Nitragin.—The experiments with this preparation have been continued with results that must be considered as gratifying. Clover was the legume under trial. The crop of the second year's growth from inoculated seed was very much larger than that from the untreated seed. A striking illustration is given, taken from a photograph of the growing clover.

Soft Pork Investigation.—The work in connection with this inquiry has engaged the greater part of the time of the chemical staff for the past four months, and as a consequence a very large amount of data has been amassed. This investigation is still in progress.

The object of this research is to ascertain, if possible, the cause or causes that lead to the development of 'soft' or 'tender' pork. Softness is a quality that very much reduces the price of bacon in the English market, and since England is Canada's chief market in this commodity and the pork packing industry has for some years past assumed very large proportions, the importance of this inquiry is obvious.

The series of experiments now in course constitute a number of feeding trials, employing neaily 200 animals, under the control of the Agriculturist, and includes the analysis and physical examination of the fatty tissue of the pigs. It is confidently hoped that this investigation, when completed, will furnish results which will allow us to draw definite conclusions regarding the cause or causes of the condition referred to, and thus enable us to furnish information of value to pork producers.

The preliminary report herein gives our data that established the fact that this quality of softness is due to the presence of what might be termed an excess of olein. Olein is a normal constituent of pork fat, and it is only when its natural relation to the other fats present (palmitin and stearin) is disturbed in the direction indicated that it becomes a matter for investigation.

Well Waters.—Of the number received, we here report upon 49; others have been sent, but for one reason or another have been disqualified and not analysed. We have every reason to believe that this branch of our work is widely appreciated by farmers and dairymen, and that it has been fruitful of good results.

Correspondence and Meetings Attended.—From November 30, 1898, to December 1, 1899, 1,267 letters were received and 1,595 dispatched. It is scarcely necessary to add that this phase of our work is to be regarded as one of considerable importance and one, as our statistics show, that is constantly increasing in its demand upon our time.

Addresses have been delivered at a number of the more important agricultural conventions in Ontario, New Brunswick and Nova Scotia during the year.

Samples received for Analysis.—The following schedule denotes the number and nature of the samples received for examination since the writing of our last report, and further, gives the approximate number of these, which for want of the necessary time, still await our attention.

SAMPLES received from Farmers for Examination and Report, November 30, 1898, to December 1, 1899.

Samples.	British Columbia	North-west Territories.	Manitoba.	Ontario.	Quebec.	New Brunswick.	Nova Scotia.	Prince Edward Island.	Newfoundland.	United States.	Total.	Number still awaiting examination.

Tuberculin.—By direction of the Department of Agriculture, we have prepared and forwarded to veterinary surgeons during the twelve months ending November 30, 1899, 1,030,740 minims of tuberculin, equivalent to 17,179 doses—a quantity practically double that sent out the year previous. This has entailed a very large amount of work, consuming, of necessity, a considerable portion of the time of the division.

Reports on 'Spraying for Mustard,' and the 'Preservation of Eggs,' giving an account of certain experiments conducted by this division, have been handed to the botanist and poultry manager, respectively, for insertion in their reports.

Assistant Chemist.—Mr. A. T. Charron B.A., has continued to do most efficient work, rendering assistance of the greatest value in the prosecution of the many and varied branches of research undertaken by this division. It is very largely due to Mr. Charron's ability and industry that I am enabled to present many of the data contained in this report.

For several years past, as is well known, we have been unable to keep up with the work asked of us, making a further increase to the chemical staff a matter of serious consideration. To meet this demand, and more especially at the present time to enable us to cope successfully with the large amount of analytical work connected with the soft pork investigation, Mr. H. W. Charlton, B.A.Sc., Toronto, was appointed second assistant chemist. Mr. Charlton entered upon his duties on November 1, and, although a month only has passed, I can bear testimony to his faithful and careful work. His application is both assiduous and intelligent, and I feel sure he will prove an efficient and reliable man.

The duties in connection with the clerical work of the division, including stenography, have for a number of years past been very largely discharged by Mr. J. F. Watson, to whom my thanks are due for a continuance of good and careful work during the year just closed.

New Chemical Building.—Since August of the present year we have been occupying the new laboratories, erected to replace those injured by fire in 1896. The building contains two laboratories with offices for the chemist and assistants on the main floor, store rooms for chemicals and apparatus in the basement, and rooms for grinding and the preparation and storage of samples, photographic purposes, &c., on the second floor. The laboratories are commodious and well arranged, and I have no hesitation in saying that the work of the Chemical Division will be much facilitated by the increased accommodation that this building, specially designed for chemical investigations, will afford us.

I have the honour to be, sir,
Your obedient servant,
FRANK T. SHUTT,
Chemist, Dominion Experimental Farms.

CANADIAN SOILS.

Of the soils received since the issue of our last report, very few, for want of sufficient time, have been submitted to complete analysis. Such samples as were of virgin soil and represented large areas, have, as a rule, been reserved until opportunity will permit of full investigation. The greater number forwarded, however, have been from cultivated fields, and consequently to be considered as 'worn' or partially exhausted soils. These, for the most part, have received a partial examination, and been reported on to the senders. Of the former class (virgin soils) two notable instances have been analysed. We here present the results obtained, with conclusions drawn therefrom.

From Dauphin, Manitoba.—The correspondent forwarding this soil says: 'It is a sample from about 100 acres which is flooded with water for a considerable time each summer. It is covered with willow scrub and grass tall enough to cut for hay. The land can be drained at a reasonable expense, and I should like to know if it would make good wheat land when drained, as, if not, I would leave it for pasture.'

This soil is probably to be regarded as representative of those lands immediately surrounding the lakes and subject to more or less flooding during the early part of the season.

The soil as received is black loam, showing a few particles of marl. On drying, it cakes into somewhat hard masses.

ANALYSIS OF AIR-DRIED SOIL.

	Per cent.
Moisture	6·90
Clay and sand, &c. (including 54 per cent coarse sand)	64·09
Organic and volatile matter	10·65
Oxide of iron and alumina	12·00
Lime	1·76
Potash	·64
Phosphoric acid	·20
Nitrogen	·338

The following figures represent, approximately, the composition of the soil (air dried) as regards its chief constituents :—

Moisture	10·00
Organic (vegetable matter)	11·00
Clay and fine sand	22·00
Coarse sand	54·00
Carbonate of lime	3·00
	100·00

The soil showed no trace of acidity or sourness. Careful examination was made for 'alkali,' but with negative results. It is free from all soluble saline matter that would be injurious to crops.

It is evident from the above data that this soil is rich in all the essential elements of plant food; indeed, as regards nitrogen, phosphoric acid, potash and lime, it compares very favourably with soils of well recognised fertility. The proportions of clay, sand and organic matter are such, I believe, as would make it a fairly good wheat soil, though the percentage of clay is not as high as in the wheat soils of the Red River Valley. The, comparatively speaking, large amount of lime present would enhance its value for wheat growing. The mechanical condition of the soil is such as to indicate the necessity of thorough drainage. To bring the soil into condition it would, I think, be a wise plan to sow with oats or grasses for a year or two. This would improve the tilth and make the soil more suitable for wheat growing.

From Notre Dame, Kent Co., N. B.—Two soils sent by a correspondent, who writes concerning them as follows: 'I send you to-day samples of virgin and cultivated soils, marked No. 1 and No. 2, respectively. They are are taken according to your instructions and may be considered as representative, not only of the farm, but also of this district. The subsoil is heavy clay. Please advise as to crops and fertilizers.'

These are grayish-red loams in which sand predominates, of fair tilth, and showing some root fibres. There is but little difference in appearance between No. 1 and No. 2. The analytical data are as follows:—

ANALYSIS OF AIR-DRIED SOILS.

—	No. 1. Virgin soil.	No. 2. Cultivated soil.
Moisture	3·91	1·78
Organic and volatile matter	8·04	5·49
Clay and sand	73·17	81·51
Oxide of iron and Alumina	13·80	9·85
Lime	·89	·02
Potash	·51	·35
Phosphoric acid	·24	·12
Nitrogen	·158	·113

The most remarkable feature in the above results is that in all the essential constituents of plant growth—nitrogen, potash, phosphoric acid and lime—the cultivated soil shows percentages much smaller than those in the virgin soil. Since we must suppose, from the information furnished, that the cultivated soil was originally identical, or practically so, with the virgin soil, the analysis of which is here given, it is evident that great exhaustion of fertility has taken place, due, no doubt, to successive cropping without any adequate return of plant food. We have in these soils an important lesson most strikingly illustrated, and we commend the careful study of the above data to those interested in the question of soil impoverishment and improvement.

Again it is to be observed that the organic matter (humus) has also been much reduced by cultivation. This constituent, though not directly used as food by crops, is the natural storehouse and conservator of plant food, as well as the factor that regulates soil moisture and warmth, essential to crop growth. We have here, then, brought before us another way in which soils are seriously impaired by improper and injudicious farming.

The economic improvement of this soil would, necessarily, include, first, the application of organic manures. As in all probability there would not be sufficient barn-yard manure to bring up the land, recourse must be had to green-manuring, that is, the turning under of a growing crop, preferably clover. The crop from 8 to 10 pounds of clover seed (which may be sown with any of the cereals without diminishing the yield of grain) will, on ploughing under late in the autumn, enrich the soil to an extent equal in many respects to an application of 8 to 10 tons of ordinary barn-yard manure.

Secondly, an application of lime is needed, for the soil is deficient in this element. Twenty to forty bushels of lime per acre every fourth or fifth year would undoubtedly give a good return. If wood-ashes could be obtained at a reasonable price, they are to be preferred, since they furnish potash and phosphoric acid in addition to lime. As clover is a plant that more particularly responds to lime and potash, the benefit of such an application would first be to this crop, but as the turned under clover decays, these mineral constituents would be liberated for future use by the cereals, grass or roots, as the case might be.

THE ECONOMICAL IMPROVEMENT OF EXHAUSTED SOILS.

The examination of a, comparatively speaking, large number of cultivated or, more properly speaking, partially exhautsted, soils received from farmers during the past five

years has afforded the writer an excellent opportunity of ascertaining the chief deficiencies of such soils. Considerable experience has also been obtained indirectly regarding the economical renovation of these, for we have received the reports of many agriculturists who have carried out our suggestions respecting the treatment of such lands. It may not, therefore, be altogether uninteresting to our readers—especially to those in districts where it becomes a matter of necessity to clear up new land, in order to procure remunerative crops—if we place on record a brief statement regarding the conditions of these soils and the cheapest and most effective methods for reclaiming them and restoring them to their original virgin fertility.

These soils are of all classes, ranging from heavy plastic clays to light porous soils, and though these two types require somewhat different treatment, the effect of continued cropping without an adequate return of plant food has been found to be much the same in both. It will be in order, therefore, to first consider what the general results of an irrational method of farming have been and then to point out the remedial agencies that are to be used to make the soils once more productive.

Effect of Continuous Cropping Without the Application of Manure.—Every arable soil possesses its stores of plant food in what may be termed two forms—though there may not be any strong line of demarkation dividing them—inert or locked-up and available. The former is practically of no value to the growing crop (though by good culture its conversion into assimilable forms constantly takes place); the latter is in a condition to be immediately made use of by the plant and built up into its tissues, root, stem, leaf, and seed. Soils of low productiveness, but which originally gave paying crops, are those whose stores of available food have been drawn upon until but very small quantities remain. This we have proven by chemical analysis. One of the first mineral elements to show depletion is lime.

Again, on comparing the analyses of such soils, the fact is revealed that the vegetable matter or humus has, in a large measure, been dissipated or destroyed by cropping during a number of years, and that with the humus the nitrogen has also diminished. The importance of a due amount of humus is difficult to over estimate. Not that in itself it nourishes plants, but that it is the natural store-house which conserves plant food from waste, presenting it in compounds particularly acceptable for crop nutrition and use, and that it is the one great regulator of a soil's moisture and temperature.

We have already referred to the fact that the elements necessary for plant nutrition are present in soils in two conditions, as it were; for the most part, in insoluble inert forms, but also, to a small degree in combinations soluble in water or readily dissolved by the slightly acid exudations of rootlets, and hence at once useable by plants. Recent research in the chemistry of soils goes to show that the basic humates, i.e., the mineral elements found in combination or connection with the soil humus, furnish more particularly this available plant food. As the humus decreases we are to understand then that as a general rule not only the percentage of nitrogen decreases, but also that the percentages of available phosphoric acid, potash and lime decrease.

Since the difference between a small yield and a large one is frequently a matter of water supply only, it is apparent that a consideration of that agency which tends to its preservation in proportions best suited for plant growth is worthy of our most serious attention. Neither clays nor sands, unless duly provided with vegetable matter, can withstand seasons of drought; the first has shed the rain as surface water; the latter, has allowed it to drain through and out of the reach of the crop's roots. Semi-decayed vegetable matter, by rendering heavy loams more porous, renders them pervious to the falling rain and melting snow, and then by its absorptive qualities serves to retain this water for crop use. In light soils, this latter property is brought prominently into play, rendering them able to support and nourish a crop otherwise quite impossible in dry seasons.

In addition to its useful function in retaining moisture, humus has a most beneficial effect upon a soil's texture, rendering clay loams more friable and mellow and allowing air (which is as necessary for the life of roots as water or food) to freely per-

meate their mass. It also serves to compact and otherwise improve the physical or mechanical condition of light and sandy soils. Without extensive root development there cannot be an abundant production of stem, foliage and seed; this is only possible in a soil with fair mechanical condition, one in which the roots can freely forage for their food.

Before leaving this brief review of the part that humus plays as a soil constituent, we must refer to the useful purpose it serves in furnishing food for bacteria or germs, microscopic plants, which live in myriads in all fertile, aerated, moist and warm soils, and which among other functions perform a most valuable work in converting nitrogenous organic compounds into nitrates, the only form, as far as we know, in which farm crops, other than legumes, can obtain the nitrogen necessary for their growth. We must also suppose that these germs serve in some degree towards the predigestion of the mineral constituents of humus, thus preparing them for assimilation by plants of a higher order. This seems evident from the fact already mentioned, that the percentages of mineral humates largely indicate a soil's fertility.

To sum up, we shall narrate briefly the features that characterize partially exhausted soils and those of low productive power, and give some of the more important economic means whereby such soils may be improved.

1. *Poor Texture.*—Better and more careful and thorough tillage is required to render them friable, porous and mellow. If a heavy clay loam, drainage will be found necessary, indeed essential. This is the true and only remedy for heavy, wet and sour lands and those underlaid by a hard and impervious subsoil. Drainage deepens the surface soil by lowering the water level, and thus allows the roots an opportunity to seek their nourishment at greater depths than is possible in a water-soaked soil. It allows a soil to become aerated, a condition essential to the welfare of living roots. Drained soils are moister in dry seasons and drier in wet weather than those undrained. Occasional subsoiling, which is simply a loosening of the layer immediately beneath the surface soil, will be found of great value to soils underlaid by hardpan.

Thoroughness in working a soil is also of great value in promoting tilth or good texture. A hard, cloddy soil is an uncongenial medium for the growth of farm crops. Clay soils should not be worked while wet, if possible, for such tends to puddling and plasticity, destroying their porosity and drainage power.

2. *Deficiency of Humus and Nitrogen.*—We may take it for granted that a lack or abundance of the former means a lack or abundance of the latter. Constant working and cropping must diminish the stores of these valuable constituents, making it absolutely necessary that all lands (save, perhaps, those in pasture) should from time to time receive an application of a nitrogenous organic fertilizer, if fertility is to be maintained.

Naturally, the manure from farm animals takes precedence as a source of organic matter and nitrogen. Unfortunately, on many farms, there is not sufficient produced to keep all the land in good heart. A very grave mistake has been made by many farmers in this respect, which must be rectified if the soil is to be brought again to its original productiveness. Dairying and stock raising if more generally practised would soon have their effect upon the soil. It has been the continuous growing of grain crops and potatoes and the selling of these products to the exclusion of other branches of farming that has caused the impoverishment of much of our arable land in the older provinces of the Dominion.

Possibly a worse feature than the deficiency of manure is the waste of it that ensues on so many farms. First, there is the loss by drainage of much of the liquid portion in the stable, cow house, and pig pen, and then follows leaching and excessive fermentation in the barn-yard. We do not hesitate to say that losses from these causes frequently amount to from one-third to one-half, or even more, of the original value of the manure. The solid and liquid portions together, as voided, would contain approximately three-fourths of the plant food present in the feeds used, the liquid part containing practically all the immediately available constituents, and hence by far, the more valuable. It, therefore, behooves every farmer to see that the floors of the buildings in which animals are kept are sound and water-tight and that sufficient bedding is used to soak up and

retain the liquids. In this connection, we would make two suggestions. The first is to cut the straw used for litter, and thus increase its absorbent power; the second is, to use in addition to the straw bedding in the cow house and piggery, a certain quantity of air-dried weathered muck, when such material can be readily obtained, as is frequently the case. Muck not only contains a considerable amount of plant food, especially nitrogen, which is set free by the subsequent fermentation in the manure pile, but by its great absorbent powers retains and saves from loss, as we have pointed out, the most valuable part of the manure. Air-dried muck frequently contains 75 per cent or more of vegetable matter. This by composting is converted into humus-like compounds and hence it is obvious that the employment of this naturally-occurring fertilizer in such a way as we have outlined is particularly valuable for such lands as we are now discussing.

A further important source of humus and nitrogen is green manuring; that is, the turning under of a green crop. For this purpose, we advocate especially the legumes, since they alone have the power (through the agency of certain germs that reside in the nodules on the roots) to assimilate free nitrogen from the air, thus enriching the soil with the most costly of all forms of plant food from a source otherwise unavailable. A good crop of Red or Mammoth clover turned under will furnish as much nitrogen to a soil per acre as a dressing of 8 to 10 tons of ordinary barn-yard manure. The benefits of this method of manuring (which indeed are hard to over-estimate) are stated at length in the report of this Division for 1895. On soils too poor to grow clover, a beginning must be made with buckwheat or rye. These crops ploughed under for a year or two and the soil further enriched with a dressing of wood-ashes (or a fertilizer supplying potash, phosphoric acid and lime) will be all that is necessary to furnish a condition suitable for the growth of clover.

3. *Sourness and Deficiency of Lime*—Since the former is often the result of the latter, it naturally follows that these conditions are frequently found in the same soil. It is also obvious that improving the soil as regards its lime content at the same time corrects sourness. Acidity or sourness is inimical to crop growth; deficiency in lime means not only the lack of an element necessary for plant nutrition, but also an unfavourable condition for nitrification of the humus.

We have in past reports explained at length the many valuable functions—chemical and physical—which lime performs in the soil. It will, therefore, be only necessary to here indicate how the farmer may obtain an indication of the amount of lime in a soil, and enumerate the sources which he can draw upon to furnish this element.

To ascertain if a soil is sour or deficient in lime, put a few ounces of it in a tumbler and add approximately an equal quantity of water; stir well and allow to settle. Place a small piece of blue litmus paper (obtained very cheaply at any druggist) in the supernatant water for a few moments. If, on withdrawing it and allowing it to dry, it is noticed that the blue color has been changed to red, the soil is sour. (The change of colour will be the best noticed if only one-half of the slip of litmus paper has been immersed.) Now add a tablespoonful of strong vinegar to the soil and water in the tumbler. The absence of effervescence or very slight effervescence only will indicate a deficiency of available lime.

To supply lime and at the same time to correct sourness, 20 to 40 bushels of lime per acre may be used. After being allowed to air-slack in small earth-covered heaps upon the field, it should be thoroughly incorporated with the surface soil by shallow ploughing or harrowing, or simply the latter, if the lime has been applied to the ploughed field. Lime has a tendency to work down, so should never be deeply ploughed under.

Marl is a very valuable source of lime for agricultural purposes. It may be frequently found in beds underlying deposits of swamp muck. It is much more 'mild' and slower in its action than lime, and can be applied in quantities much in excess of those given for lime, without injury to the soil.

Wood-ashes, in addition to 5 to 6 per cent of potash and 1 to 3 per cent of phosphoric acid, furnish lime to the extent of 30 to 35 per cent. It is obvious, therefore, that in them we have a very complete fertilizer for supplying mineral plant food. It is

a mistaken policy on the part of the farmer, we have always held, to sell wood-ashes, which really represent fertility from his soil, for such a paltry recompense as he usually obtains from ash collectors. By reason of the potash and lime they contain, wood-ashes are of particular value for encouraging the growth of clover—and a rotted clover sod is an excellent preparation for a crop of corn, roots or cereals. An average dressing of wood-ashes might be placed at 50 bushels per acre, though, if the supply be limited, half that quantity would undoubtedly show good results on such soils as we are now considering, namely, those that are sour or deficient in lime.

FERTILIZERS AND AMENDMENTS.

MARSH MUD.

A sample of this material from the Habitant River, Cornwallis Valley, N.S., has recently been examined at the request of the Hon. F. A. Borden. The data obtained are tabulated as follows :—

Analysis of Marsh Mud (Air-dried.)

Moisture	3·45
Organic and volatile matter	4·14
Clay and sand	75·59
Oxide of iron and alumina	11·71
Lime	1·40
Magnesia	·48
Common salt (sodium chloride)	·86
Total phosphoric acid	·15
Available phosphoric acid	·05
Total potash	·25
Available potash	·06
Nitrogen	·128

In all essential features, this marsh mud or deposit resembles closely many samples from the Bay of Fundy, previously examined in our laboratories. Though doubtless a material that might improve many soils, it cannot be regarded in the same light as a commercial fertilizer, for its percentages of essential elements of fertility—nitrogen, potash and phosphoric acid—are not large; indeed a careful comparison reveals that, as regards composition, this deposit is not richer than many soils of average productiveness.

Important features in the above analysis are the determinations of *available* potash and phosphoric acid. We have for a long time been led to think that the greater part of the benefit accruing from the use of these deposits might be due to a comparatively high availability of the mineral plant food, since, as we have already seen, the total amount of such is by no means large. Accordingly, this sample was examined by the Dyer method (see report of this Division for 1897, page 158), and as a result the percentages of 'available' phosphoric acid and potash above recorded were obtained. Though these percentages, from the ordinary point of view, would be considered small, it is to be remarked that, compared with similar data from good, fertile soils, they are remarkably large. Thus, compared with a rich soil from British Columbia, we have the following :—

—	Soil from British Columbia.	Marsh Mud, Cornwallis, N.S.
Potash	·23	·25
Available potash	·005	·06
Percentage of total potash available for plant use	2·2	24.00
Total phosphoric acid	·19	·15
Available phosphoric acid	·010	·05
Percentage of total phosphoric acid available for plant use	5·66	33·33

There results verify our conjecture and show that a very large proportion of the potash and phosphoric acid is present in a condition at once useable by crops. If an application equivalent to 100 tons of the air-dried material per acre were made, there would be furnished to that area, approximately, 120 pounds potash and 100 pounds phosphoric acid immediately available for plant use—no inconsiderable amounts.

Further, in all probability, much of the benefit that is derived from this material is due to its mechanical effect upon the soil. As these deposits vary in their proportions of sand and clay, their results will depend much upon the nature of the soils to which they are applied. It thus may happen that the frequent application of a 'mud' rich in clay may do positive harm to a heavy soil, destroying its tilth; while the same material on a light soil would give excellent results, and vice versa. Close observation on the part of the farmer is needed in this matter.

The common salt present is of no direct value as plant food, but serves, undoubtedly, in the liberation of inert or locked-up plant food, especially lime and potash, in the soil. It is for this reason that the continued use of salt muds exhausts, rather than enriches, the soil in these elements, and the necessity of supplementary manures is made obvious.

It is also probable that soils frequently 'mudded' become comparatively poor in humus, and consequently in nitrogen, a condition that always reduces productiveness. For this reason, a certain amount of an organic manure, such as would be supplied by barn-yard manure, should be applied in conjunction with the mud.

A consideration of these facts, therefore, while leading us to acknowledge and recognize the value of marsh mud, at the same time urges its judicious and intelligent use, and in conjunction with other forms of plant food. Too many have erred in its indiscriminate application, under the impression that it was a complete fertilizer, and could be used in any quantity without endangering the condition of the soil.

Through the kindness of Professor Wm. F. Ganong, Smith's College, Northampton, Mass., who is at present engaged in an exhaustive study of these deposits with a view of determining the relation between their composition and flora, I am enabled to present the following data obtained from a mechanical examination of the soil. My thanks are also due to Dr. G. E. Stone, Agricultural College, Amherst, Mass., under whose direction the analysis was made.

Mechanical analysis of the sample of Cornwallis Soil.

Water	3·400
1. Organic matter	3·200
2. Gravels from 2· to 1· mm. diam	·125
3. Coarse sand, from 1· " ·5 " "	·260
4. Medium sand " ·5 " ·25 " "	1·485
5. Fine " " ·25 " ·1 " "	4·060

SWAMP MUCK.

In the subjoined table we give the analytical data obtained from the examination of certain samples of swamp muck received from farmers during the past year.

As in former reports (1894 and 1896) we have written upon this subject at length, stating the origin, composition and uses of this and allied materials, it will only be necessary here to remind our readers that while crude muck applied directly to the land is of but little manurial value, its plant food can be made available by composting, as with barn-yard manure; and, further, that as an absorbent in and about the farm buildings, indeed, wherever there is liquid manure likely to go to waste, it can be employed to

advantage. As a manure, its chief value lies in the humus and nitrogen it contains. The amounts of these constitutents, considered in connection with the degree of decomposition of the muck, therefore, determine the relative value of any particular sample.

ANALYSIS of Swamp Muck (air-dried), 1899.

No.	Locality.	Sender.	Nitrogen. Per cent.	Nitrogen. Pounds in one ton of material, air-dried.	Organic and volatile matter.	Sand and clay.	Mineral matters soluble in acid.	Water.

Brief notes on the above may be given as follows :—

No. 1. 'From a swamp from 5 to 6 acres in extent, ranging 1 to 6 feet in depth, thinly covered with stunted growth of juniper, spruce, fir, ash and swamp maple, with an undergrowth of alder bushes, ferns and tall grasses.'

An excellent sample, being composed almost entirely of semi-decomposed vegetable matter, and containing above the average per cent of nitrogen, would prove valuable for composting, and also as an absorbent.

No. 2. "Occurs in a dip or basin about half an acre in extent, depth of deposit from 6 inches at edge to 3¼ feet in middle. Surface covered with undergrowth."

Not very well decomposed, but practically free from clay, sand, &c. As regards nitrogen, it is of average quality. Would make a useful absorbent.

No. 3. While not the equal in quality of the best samples, it is of sufficient value to use. It should, however, be thoroughly composted before being applied to the soil.

No. 4. Of fair average quality, and should prove a useful source of humus and nitrogen, after being thoroughly composted.

Nos. 5 and 6. 'From a large bog within a mile of several farms. Deposit is many feet deep.' A very good muck, though not above the average in nitrogen. It is practically free from inert matter. It requires weathering and fermentation, and then would prove a useful manure. Could be used in air-dried condition as an absorbent in and about the farm buildings. Samples are practically identical.

No. 7. 'From below a deposit of muck.' Not equal in quality to ordinary swamp muck, and it would be better to use the overlying deposit, since the latter would be richer in vegetable matter and nitrogen.

No. 8. 'From an old beaver pond; deposit 6 to 9 feet deep. Taken 8 feet below surface.'

No. 9. From the same deposit, taken 2 feet below surface. No. 9 is the better sample, being richer in nitrogen and organic matter, and containing less clay.

No. 10. A fair muck of average quality. Requires thorough fermentation by composting, according to one or other of the methods given in previous reports.

No. 11. Woody in character and but little decayed. Practically of no manurial value in its present condition, but could be used probably to advantage after air-drying as an absorbent of liquid manure.

No. 12. Slightly above the average.

No. 13. 'From a deposit overgrown with cedars, birch and spruce, varying in depth from 3 to 4 feet.' An excellent muck, rich in organic matter and nitrogen and practically free from sand and clay. It, however, requires weathering and composting before it will furnish its plant food in available forms. Air-dried, it should act as a good absorbent.

Nos. 14 and 15. 'From upper and lower layers, respectively, of desposit.' Both are fair samples, but the upper (No. 14.) is somewhat the better of the two.

Nos. 16 and 17. 'Apparently from an old river or lake bed, the deposit lying between hills, and varying from 150 feet to 1,000 feet in width. About 9 feet deep and underlaid with shell marl." As a soil, No. 16 would probably give better results. It should be well drained and treated with lime, or better still, with wood-ashes at the rate of 50 to 75 bushels per acre. This would correct sourness and supply the necessary mineral constituents, and make it a good soil for market garden stuff. A dressing of good barn-yard manure at the outset would be valuable in starting decomposition and furnishing immediately available plant food.

As an absorbent and material for composting, No. 17 is to be preferred.

No. 18. This is not, properly speaking, a swamp muck, but is rather of the nature of a soil rich in organic (vegetable) matter. Of very little, if any, value as an absorbent.

No. 19. This is not equal to the best samples, but worth composting, if the soil of the farm stands in need of humus.

TANNERY ASHES.

Numerous inquiries have from time to time been received as to the value of ashes from tanneries as a fertilizer. As we had no definite information on this matter, we determined to submit to for analysis two samples of such ashes forwarded by a correspondent in Orillia—one, collected directly from the furance ; the other, taken from a heap of the exposed ashes. The fuel producing these ashes is stated as "spent tan bark and a few pine slabs.' Our results are as follows :—

Analysis of Tannery Ashes.

———	From Furnace.	From Heap.
Moisture	0·24	40·32
Loss on ignition (charcoal, &c.)	5·30	4·30
Insoluble mineral matter	6·95	3·76
Phosphoric acid	2·13	1·00
Potash	3·05	·98

The presence of a large percentage of water in the exposed ashes and the evident fact that they had suffered considerable loss through leaching, makes them much less valuable, weight for weight, than the ashes taken at once from the furnace. The latter practically contain one-half the amount of potash found in good unleached wood-ashes, and consequently may be considered as worth approximately half the price of this well known potassic fertilizer. Like wood-ashes, these tannery ashes possess a certain well marked agricultural value for the lime and phosphoric acid they contain.

WOOD-ASHES.

The analysis of a sample of wood-ashes forwarded by Messrs. Reford & Co., Montreal, showed their composition to be as follows :—

	Per cent.
Moisture	2·26
Loss on ignition (charcoal, &c.)	5·62
Insoluble matter (clay, sand, &c	17·36
Phosphoric acid	2·21
Potash	6·22

Commercial wood-ashes necessarily vary somewhat in composition; but good samples should range between 5% and 6% potash, and 1·5 per cent to 2·5 per cent phosphoric acid. It is evident, therefore, that this sample may be regarded as quite equal to the standard of good commercial grades.

FISH POMACE.

The value of fish waste as a supplier of nitrogen and phosphoric acid has been set forth in previous reports of this division (see report for 1896). In the early part of the present year a further sample was analysed in our laboratories. This was forwarded by Mr. H. D'Almaine, farm superintendent for Sir Wm. Van Horne at St. Andrews, N.B., and had been prepared from herring, quantities of which at certain times in the year, I understand, can only be used in the preparation of fertilizer.

Our analysis furnished the following results ·

	Per Cent.
Moisture	40·23
Organic and volatile matter	46·68
Mineral matter	13·09
	100·00

	Per Cent.	Lbs. per ton.
Phosphoric acid	2·39	47·8
Nitrogen	5·99	119·8

Assigning to nitrogen and phosphoric acid the values of 10 cents per lb. and 5 cents per lb., respectively, a moderate valuation, this fertilizer would be worth $14.37 per ton.

Farmers along the coast of the maritime provinces in many places could obtain fish offal for the hauling, and it seems a great pity they do not make more use of what might easily be converted into a most valuable manure. To furnish information regarding the preparation of such a fertilizer, the following account has been written. There is much land, especially in Cape Breton, that might with advantage receive a dressing of a manure supplying organic matter in addition to the elements of fertility, and it is hoped that the subjoined information will lead many to secure this valuable material which, for the most part, is now wasted and, indeed, frequently, as in the neighbourhood of fishing stations, &c., proves a nuisance and a menace to health.

Preparation of fish waste upon the farm.—Some method of composting must be followed, since the artificial drying of the fish or offal and extraction of fat resorted to by the fertilizer manufacturers are too costly for the farmer. If swamp muck exists in the neighbourhood, no better composting substance could be used. After being dug and piled, it should be allowed to thoroughly air-dry and weather. If, however, muck is not accessible, good loam will answer. The compost heap should be made of alternate layers (3 to 6 inches thick) of the fish waste and muck, a layer of the latter being uppermost. Sprinkle each layer of fish offal with quick lime or wood-ashes. A convenient height for the compost heap is from 4 to 5 feet and it is advisable to protect it from rain

with a rough roof of boards, and thus prevent leaching. The heap should be turned over once or twice to check excessive fermentation and to make the mass uniform. If during the fermentation the composting mass becomes dry, it should be moistened. Composts should be kept damp, but not saturated with water. The length of time to bring the whole mass into fine condition will depend much upon the weather; if the compost is made in summer, probably three to four months will suffice.

In order that this fish compost may supply all three of the chief elements of plant food, we counsel the addition of wood-ashes (to furnish potash) at the rate of 200 lbs. per 500 lbs. of fish, before composting. If wood-ashes are not obtainable, kainit (a German potash salt containing 12 to 13 per cent potash) at the rate of 100 lbs. per 500 lbs. fish waste, can be used.

Method used in France.—It has for many years been a common practice in France to preserve fish waste by the use of quick-lime. The fish offal and quick-lime are placed in alternate layers in a hogshead or other suitable receptacle. The moisture of the fish slakes the lime and a so-called albuminate of lime is formed. After a few weeks, the mass is thoroughly turned over and mixed, and spread in thin layers to dry. The resulting material can be kept without offence for a long time if preserved in a dry place. If dry, unleached wood-ashes were used (replacing half the amount of quick-lime) or kainit added in the proportion already indicated, the resulting manure would be rich in potash as well as in nitrogen and phosphoric acid.

Since fish compost readily yields its elements to growing crops, it may be applied in the spring. It should be harrowed in, or at most but slightly turned under. Its best results are obtained on medium soils; that is, those that are characterized as neither too light nor too heavy.

THE FERTILIZING VALUE OF SLUDGE AND POUDRETTE.

In the various systems of sewage purification by precipitation adopted by cities, a product is obtained from the settling vats or reservoirs which is generally known as sludge. The composition of this material will, naturally, vary with the concentration of the sewage, the nature and amouunt of the precipitant (lime, alum, &c.,) and the degree to which it is subsequently dried; hence, the fertilizing value is a matter of close inquiry. For want of correct information, we fear this value is frequently exaggerated, and we accordingly insert the following data obtained in our laboratories this year from a sample forwarded from Hamilton, Ontario. The analysis was made at the request of several large fruit growers in the Niagara district, who had been purchasing or who were considering the purchase of this fertilizer for their vineyards and orchards.

Sludge from Hamilton Sewage Disposal Co.

	Per Cent.
Moisture	31·75
Organic and volatile matter	39·05
Mineral matter	39·20
	100·00
Clay, sand, &c., insoluble in acid	9·66
Alumina (plus small amount of oxide of iron)	4·74
Lime (CaO)	9·23
Magnesia (MgO)	10.40
Phosphoric acid (P_2O_5)	·69
Potash (K_2O)	·19
Nitrogen	·84

Comparing these figures with those recorded in England and Germany for similar materials, the quality of this sludge appears to be somewhat above the average; the

percentages of the essential elements of fertility, it will be seen, however, do not approximate those found in commercial fertilizers, nor can we suppose the plant food in sludge to be as available as in the latter. It is quite evident that these facts, apart from other considerations, would not permit its transportation to any great distance with profit; but, providing it does not affect injuriously the condition of the soil, that it could be got cheaply, and that it was supplemented with other manures (more especially those containing potash), it could be used locally to advantage.

A feature worthy of notice to those whose soils are deficient in lime, is the comparatively large amount of this element present in this sludge, the greater part of which exists in the fresh material as slaked lime, but which becomes converted into the form of carbonate of lime by long exposure.

Unless sludge is thoroughly weathered, as by exposure throughout the winter, it is refractory and not easily incorporated with the soil. This is a serious objection to its general use. Again, heavy clay loams might be injured by a continued use of such a plastic, mud-like material, and we could, therefore, only advise its trial upon sands or gravels, especially those in need of lime and organic matter.

The term poudrette is applied to the dry, powdered sludge, a material usually of greater manurial value than sewage, by reason of its containing somewhat larger amounts of plant food, and being in a better mechanical condition. A sample received from Toronto a few years ago, the product of a process under trial there, furnished the following data:—

Poudrette from Toronto.

	Per cent.
Moisture	3·94
Organic and volatile matter	40·91
Mineral matter	55·15
	100·00
Clay, sand, &c., insoluble in acid	34·05
Oxide of iron and alumina	13·65
Lime (CaO)	2·07
Magnesia (MgO)	·33
Phosphoric acid (P_2O_5)	1·24
Potash (K_2O)	·21
Nitrogen	2·04

As analysed, this poudrette is considerably richer in plant food than the sludge, due chiefly to the smaller quantity of water it contains.

Sludge and poudrette are said to be rich in germs of the nitric ferment, which are necessary for the conversion of soil nitrogen into nitrates, the form in which farm crops obtain their supply of this element. It is probable that the beneficial result from the use of these materials is in part due to the presence of these nitrifying germs.

FODDERS AND FEEDING STUFFS.

BROAD LEAF HAY *(Spartina Cynosuroides.)*

In Bulletin No. 19, issued in 1893, we published data showing the composition of broad-leaf hay from grass obtained at Indian Head, N.W.T., Brandon, Man., and Sackville, N.B. The latter sample was so decidedly inferior to the others that it was thought well to repeat the analysis on another sample from the maritime provinces, and thus learn if that sent in 1893 had been cut too late for best results. We accordingly examined, during the early part of the year, a sample kindly furnished by Mr. Jas. Frier, of Shediac, N.B. The results are given in the following table, which also con-

tains, for the purpose of comparison, analyses made of timothy hay and brome grass hay of the 1897 crop on the Central Experimental Farm, Ottawa:

Constituents.	Broad-leaf Hay.	Timothy Hay.	Brome Grass Hay.
Moisture	7·00	9·72	10·76
Protein or albuminoids	4·95	5·94	6·61
Fat	3·73	5·38	4·51
Carbo-hydrates	47·87	43·25	41·01
Fibre	30·82	31·30	31·86
Ash	5·73	4·41	5·25

As regards the most important constituents—the albuminoids (sometimes called flesh formers),—broad-leaf hay is seen to fall considerably behind timothy and brome grass hay. From experiments made in the United States it appears that the digestibility of broad-leaf hay is not quite equal to that of either timothy or brome grass (cut under the same conditions) and, therefore, I think we are quite justified in placing its feeding value lower—probably 15 to 20 per cent—than that of timothy hay and brome grass hay. From our experience in the matter of grasses and their nutritive qualities, we are of the opinion that a much more nutritious hay could be obtained by cutting the broad-leaf earlier in the season than is now customary.

HAY DECOCTION OR TEA.

A correspondent in Sackville, N.B., wrote us in March last as follows: 'We have more hay here than we can sell or get stock to feed to in the ordinary way. It occurred to me that by steeping it we might get the most of the nutriment, leaving the woody portion for compost, the decoction being good for hogs and other stock. The sample I send herewith has been prepared by steeping 16 pounds of hay in about 70 pounds of hot water, the weight of the resulting decoction was 67 pounds, the difference being lost by evaporation. I should like to know its feeding value and if it could be used with economy for stock.'

The analysis of the hay decoction furnished the following data:—

	Per cent.	Per Gallon.
Total solids or extractive matter	2·06	3½ ozs.
Nitrogenous matter or portein	·48	¾ "
Mineral matter or ash	·33	½ "

The total weight of the decoction, 67 pounds (obtained from 16 pounds of hay) would therefore, contain:—

	Pounds.	Ounces.
Total solids or extractive matter	1	6
Nitrogenous matter		5
Mineral matter or ash		3½

The use of hay tea, supplemented by a little linseed and shorts, has enabled many farmers to raise calves successfully without whole milk, but the data here presented make it extremely doubtful if such a decoction as the above contains sufficient nourishment to make its preparation profitable for adult stock or swine. It could, of course, be concentrated by simply boiling down, but whether this could be done with profit would depend largely on the price of fuel and labour. We are inclined to think that as far as dairy and fattening cattle are concerned it would pay better to feed the hay, provided it is of good quality and has been cut early i.e., before the ripening process had set in.

COTTON SEED MEAL.

This concentrated feed stuff is imported from the United States, where it occurs as a by-product in the cotton industry of the south. The hulls or envelopes of the cotton seed being removed, the kernels (which are rich in oil of considerable commercial value) are crushed and subjected to heat and pressure. By this means the greater part of the oil is separated, a residue being left, which is either sold as it comes from the mill—cotton-oil cake— or ground and shipped as cotton seed meal.

This material, recognized as a most valuable feeding stuff, by reason of its high percentage of protein (albuminoids) and its notable amount of oil or fat, is now being extensively used in certain dairying and stock raising districts of the Dominion to furnish a part of the ration. On account of its exceedingly concentrated character, and possibly the presence of some active principle not as yet isolated or determined, cotton seed meal must be used judiciously, that is, in reasonable amounts and with other feeds. Professor Henry, of the Wisconsin experiment station, in his work 'Feeds and Feeding', says that it has been fed with safety and profit to dairy cows to the extent of 5 to 6 pounds daily per head; however, such quantities are not to be generally advised, 2 pounds being probably a safe limit. For fattening steers the amount, it is stated, can be gradually increased to 6 pounds, or even more, per head, daily, though it is generally admitted that good health and thrift demand a mixture of grains or concentrated feeds—which necessarily means a less weight of cotton seed meal than that here mentioned. To those beginning the use of this feed, we would counsel carefulness, employing it at first in small amounts and always mixed with a good proportion of other feeds.

Repeated trials have shown that cotton seed meal cannot be fed to calves. It invariably, even when fed to the extent of a few ounces daily, causes an acute form of indigestion followed by diarrhœa, and is usually followed by death. Neither is it a safe or profitable feeding stuff for swine.

A sample forwarded from Dalling, Que., during the past year afforded the following data :—

Cotton Seed Meal.

Moisture	6·17
Fat or oil	8·72
Protein or albuminoids	43·19
Fibre	5·88
Carbo-hydrates	28·36
Ash or mineral matter	7·68
	100·00

The average composition of cotton seed meal as given by American authorities, is :

Moisture	8·2
Fat or oil	13·1
Protein or albuminoids	42·3
Fibre	5·6
Carbo-hydrates	23·6
Ash or mineral matter	7·2
	100·00

The only difference of note between the two is the much smaller percentage of fat in the sample analysed, evidently due to a larger proportion of the original oil being expressed than is usually the case. The deficiency in fat is to a certain extent counter balanced by slightly increased percentages of protein and carbo-hydrates.

Since inquiries are being frequently received respecting the comparative values of the more concentrated feed stuffs, we append for the information of our readers the following table, gathered from American sources, from which may be learnt the percentages of the digestible nutrients they contain :—

DIGESTIBLE Nutrients in 100 lbs. of certain concentrated feed stuffs.

——	Protein.	Fat.	Carbo-hydrates.
Oil cake (new process)	28·2	2·8	40·1
Oil cake (old process)	29·3	7·0	32·7
Bran	12·2	2·7	39·2
Cotton seed meal	37·2	12·2	16·9
Gluten meal	25·8	11·0	43·3
Pea meal	16·8	·7	51·8

If we assume that the ratio of value between digestible protein, fat and carbohydrates, to be as 3:3:1—a ratio which necessarily must be considered as only approximately correct—we ascertain the comparative feeding values of the above feeds to be as follows :—

	Approximate Feeding Values.
Oil cake (new process)	133
Oil cake (old process)	141
Bran	84
Cotton seed meal	165
Pease	104
Gluten meal	154

That is, if judiciously and rationally used, pease would be approximately worth for their nutrients $1.04 per cwt., when bran sold for 84 cents per cwt., and so on.

LAMBS' QUARTERS (*Chenopodium album*).

This weed is abundantly prevalent in Manitoba and the North-west Territories, Dr. Fletcher considering it the most common of all the weeds in those provinces. Since in many parts it has spread so as to entirely cover comparatively large tracts of land, we considered it advisable some years ago to determine its value as a fodder plant, as well as its manurial worth. An account giving the analytical data on these points was published in our report for 1890, from which we may briefly quote as follows :— 'Judging from its composition and relationship to other edible plants, there seems no reason why it (Lambs' quarters) should not make a nutritive fodder if cut young and in a succulent condition. As the plant matures there appears to be a considerable deposition of woody fibre, which would lower its digestibility considerably.' Respecting its fertilizing value or, looked at from another standpoint, the extent to which it exhausts the land, we showed that in the fresh condition one ton of the plant contained nitrogen, potash and phosphoric acid worth $2.74, and that of these three elements potash was the most abundant, practically one-half of the ash consisting of this constituent.

In the early part of the present year several samples of the seed of this weed were received from Manitoba, the letters accompanying these requesting information as to its feeding value. Thus, Mr. Thos Dand, C.E., crop correspondent, writing from Delor-

aine, says: 'We have a very large quantity of small seed this year as a residue from thrashing. This weed is on our best new cultivated land and must have been brought here in the winter by snow storms and blizzards. This district has grown at all times the very best 'No. 1 Hard' since 1886. The sample of seed goes to you by this mail and our farmers, since many of them have a large quantity of it, would be glad to have you make an analysis.'

Again, Mr. S. W. Bishop, of Sintaluta, writes under date of December 30, 1898 'I send you a small bag of the seed of pigweed or lambs' quarters, of which we have a large pile at each thrashing. This I have saved and fed to my cattle, 1 gallon each per day, and they seem to eat it readily and with relish. Will you kindly let me know its feeding value, and if it is worth saving as feed?'

We, accordingly submitted the seed to analysis, and obtained the following data:—

Analysis of Seed of Lambs' Quarters (Chenopodium album).

Moisture	9·82
Fat or oil	6·78
Protein or albuminoids	14·19
Fibre	1·27
Carbo-hydrates	63·91
Ash or mineral matter	4·03
	100·00

From these results, I judge the seed to have a comparatively high feeding value. Its percentages of fat and protein—the two most important nutrients—place it approximately, midway between corn meal and bran.

Since these seeds are very small and possess a hard integument, it seems most probable that if fed without previous grinding or boiling the greater number of them would pass through the animal undigested, in which case not only would they be of no food value, but harm would be done by their dissemination over the farm in the resulting manure.

THE CHEMISTRY OF INSECTICIDES.

PARAGRENE.

In the early months of the present year our attention was called by several large fruit growers to a newly introduced insecticide, Paragrene, a material which the manufacturers claim is fully as effective as Paris green and much cheaper.

In a letter received from the manufacturer, Mr. Fred. L. Lavenbury, New York, U.S., under date of March 31, he writes to Dr. Fletcher: 'In answer to your kind inquiry we inclose circular describing Paragrene as an insecticide. We claim that it contains 50 per cent arsenious acid, thus making it absolutely reliable and effective as a poison. It is to be used in exactly the same way and in the same quantities as Paris green. Respecting price, we have adopted a price list for the consumer which makes it impossible for the article to cost more than 14½ cents per pound for 14 pound pails; 15 cents for one and three pound packages; and 16 cents for one-half pound packages, and 17 cents for one-quarter pound packages. Paris green, of course, is sold for a considerably higher price, and our object has been to put this new insecticide at a figure that would be attractive and save the farmer considerable money.'

Believing that a knowledge of the composition of this material would be of interest to fruit growers and orchardists, we obtained a sample for analysis and found it to be a green powder, similar in general appearance to Paris green, though of a lighter colour.

On mixing with water, it remained longer in suspension than Paris green similarly treated. The mixture had a faint but still distinctly alkaline reaction. The analysis of the powder afforded the following data :—

Analysis of Paragrene.

Arsenious acid (As_2O_3)*	44·2
Copper oxide (CuO)	24·1
Lime (CaO)	3·7
Sulphuric acid (SO_3)	3·5
Acetic acid, undetermined.	

* Of this, 4·56 per cent was found to be soluble in water.

It is probable from the above that this substance is a mixture consisting chiefly of aceto-arsenite of copper (Paris green) and small amounts of white arsenic and of arsenite and sulphate of lime.

As regards arsenic, the essential toxic agent, Paragrene falls somewhat behind Paris green, which by law is required to contain 50 per cent arsenious acid. It is possible that the claim of the manufacturers in the matter of this constituent would receive more favourable support from the examination of further samples, as strict uniformity in composition is scarcely obtainable in the preparation of such substances, much depending upon the conditions under which the precipitation is made.

In the consideration of the properties of this new compound as a practical insecticide, there are two features worthy of mention. The first is the slightly alkaline character of the mixture with water, thus probably obviating the necessity of adding lime in order to guard against injury to foliage, as is the case with Paris green. Secondly, we have the fact that Paragene does not so readily settle out as Paris green after the necessary dilution with water, thus enabling an easier and more equable distribution of the poison.

A trial was made by the horticulturist with Paragrene for the destruction of potato bugs, but owing to the small quantity available for this use, Mr. Macoun thinks he has scarcely sufficient data to draw conclusions from as to its merits compared with Paris green. Further experiments will be made with it in the field next season.

KEROSENE-CARBOLIC EMULSION.

This spraying fluid is strongly recommended by Mr. Badger, of Warkworth, Ont., who used it for three sprayings for oyster-shell bark-louse and borers in December last with apparently good effect. The proportions advocated by Mr. Badger are :—

Kerosene	2 gallons.
Water	1 gallon.
Soap	½ pound.
Crude carbolic acid	2 pints.

For use, dilute 1 gallon of emulsion with 8 gallons of water.

From the above, it is seen that this fluid is the ordinary kerosene emulsion with the addition of so-called crude carbolic ocid. There was, however, a difficulty in keeping the mixture emulsified, the 'crude carbolic acid' rising very frequently to the surface after the dilution in the spray pump barrel. Our correspondent requested information that would enable him to prepare an emulsion that would not separate.

We were at first at a loss to understand how it was that the carbolic acid did not dissolve, since 1 part carbolic acid is soluble in 20 parts of water, and moreover, if it were not miscible why it should float, since carbolic acid is heavier than water. An examination of a sample of the material used, however, explained these facts satisfac-

torily. The greater part of the material is not carbolic acid, but crude oils (tarry matters), distillation products from coal tar. The carbolic acid it contains, no doubt is dissolved in making the emulsion and is sent out in the spray, though the crude oils float.

Further experiment showed us that this 'crude carbolic acid' dissolves readily and entirely in coal oil (kerosene) and that when it is thus first dissolved, and not added direct to the soap suds, the emulsion remains perfect for a long time. Such an emulsion, though diluted with eight times its volume of water, kept several weeks in the laboratory without any appreciable separation of the crude carbolic acid. Mr. Badger subsequently prepared the emulsion in the way suggested, mixing the 'crude carbolic acid' previously with the coal oil, and reported the results as eminently satisfactory. On February 16, he wrote: 'We used to-day 20 gallons of the kerosene-carbolic spray for lice on cattle, hogs and hens. In making the emulsion we followed your suggestion and mixed the crude carbolic acid with the coal oil before pouring it into the hot soap suds. When diluted it did not separate as it had previously done.'

This emulsion would appear to merit a thorough trial by those having occasion to use the ordinary kerosene emulsion.

BLUESTONE-KEROSENE MIXTURE.

A correspondent suggests that the addition of bluestone (sulphate of copper) to kerosene emulsion would furnish a spray for use on dormant trees that would, as it were, do double duty, destroying fungus spores and insect life.

This is not practicable, for the addition of a solution of bluestone to the emulsion causes an immediate separation of the constituents of the emulsion, the coal oil, together with the curdy copper-soap formed, rising quickly to the surface. For this reason such a mixture could not be readily applied, nor would it be desirable, since the decomposition that has occurred would have seriously impaired the efficacy of the spray, rendering it practically useless on dormant wood, so far as the action of the bluestone is concerned.

BORDEAUX MIXTURE AND TOBACCO WATER.

A correspondent asks if tobacco water could be used with bordeaux mixture, and thus obtain a spray that would be at once an insecticide and fungicide.

We made careful search through such literature as we had on the subject of spraying mixtures, but could not find any mention of this combination as having been used or even experimented with. Apparently, therefore, there are no results on record to draw conclusions from as to its efficacy.

Accordingly we prepared bordeaux mixture (4 : 4 : 40 formula) and made a strong decoction of tobacco. These were mixed in equal proportions. On standing it was noticed that separation of the copper precipitate occurred somewhat more quickly than in the untreated bordeaux mixture, leaving a clear, greenish-brown supernatant liquid. This, on being filtered off and tested, was found to be quite free from copper, showing that the tobacco water had not in any way interfered with the action of the lime upon the bluestone.

This result leads me to think that if applied when freshly prepared, the addition of the tobacco water would not affect the application from a mechanical standpoint, or destroy the efficacy of the bordeaux mixture as a fungicide.

The question as to whether the tobacco water by being mixed with the fungicide loses in any degree its power of destroying aphides is somewhat more difficult to answer. Further investigation is necessary before we can speak dogmatically on this point, but since the proposed plan could do no harm—and would reduce the labour of spraying in many instances—we think it is one worthy of trial.

SOIL INOCULATION FOR PROMOTING THE GROWTH OF THE LEGUMES.

THE USE OF NITRAGIN IN AGRICULTURE.

For several years past we have experimented with Nitragin*, a preparation containing the germs which reside in the nodules on the roots of legumes, with a view to ascertaining its practical value for encouraging the growth of clover, pease, and horse beans. The results given in detail in our reports for 1897, 1898, have on the whole been very satisfactory.

This year, the work has been continued with clover and horse beans, using the method that we have previously described as 'seed inoculation' and sowing the seed upon a practically pure sand which had been fertilized with muriate of potash and super-phosphate so that the plants might find a sufficient store of mineral matter to draw upon. Owing, however, to a delay in receiving the nitragin from Germany, we were not able to start the experiment till the season was advanced, and, as a consequence, the plants had not attained a sufficient size when growth ceased to allow any data of value respecting the relative weights of the crops being taken. If, as we hope, the clover survives the winter, we shall be able to ascertain what effect the nitragin may have had on the crop of the next year.

Notwithstanding this, we have an important result to report on the treated and untreated clover sown in 1898, that is, on its second year's growth. This experiment was started under the following conditions:—

The soil selected was almost pure sand, humus and nitrogen being present only in exceedingly small quantities. An area of 10 square yards was staked off and fertilized with the following mixture: muriate of potash, 4 oz., superphosphate, 12 oz. (This is at the rate of 300 pounds, superphosphate and 120 pounds muriate of potash, per acre).

On June 13, 1898, two rows of inoculated seed and two rows of untreated seed were sown in this area. On October 28, 1898, the plants from 4 feet in each row (the rows being 6 feet in length) were carefully dug and weighed.

First Year's Crop, 1898.

——	From Untreated Row.	From Inoculated Row.
Weight of foilage, green	225 grms.	270 grms.
" roots "	225 "	255 "
Total	450 grms.	525 grms.
Weight of foilage, air dried	85 grms.	105 grms.
" roots " "	70 "	91 "
Total	155 grms.	196 grms.

The crop from the inoculated seed was much more luxuriant than that from the untreated seed, and the above results show that the yield was considerably, practically 15 per cent, heavier. There is every reason to believe that this increased yield was due to the beneficial influence of the nitragin.

The remaining portions (2 feet) of the rows were left, and it was found when the season opened this year (1899) that the plants in both series had survived the winter. They made excellent growth, but those from the inoculated seed were very much larger. On July 10, 1899, this second year's growth was photographed and the plants taken up and weighed.

*For an account of this bacteriological preparation see the report of the Chemical Division for 1897.

Of the inoculated plants there were :—

Large,	23	plants, average height from root to crown...	28 inches.
Medium,	17	" " " ...	9 "
Small,	44	" " " ...	6 "
Total,	84		

Of the untreated plants there were :—

Large,	12	plants, average height from root to crown...	23 inches.
Medium,	15	" " " ...	7 "
Small,	37	" " " ...	4 "
Total,	64		

Second Year's Growth, 1899.

	Inoculated.	Untreated.
Total weight of plant (leaves, stems and roots) ..	745 grms.	252 grms.

Selecting the twenty-one largest plants of each series, we obtained data as follows

	Inoculated.	Untreated.
Stems and leaves....................	378 grms.	90 grms.
Roots................................	70 "	23 "
	448 grms.	113 grms.

These results are truly remarkable and of a most convincing nature. The luxuriance of the growth from the inoculated seed as compared with that from the untreated seed is shown very well in the accompanying photograph, which was taken immediately before digging the plants.

It is impossible to get a good crop of clover on land which is water-soaked, or, on the other hand, when there is a deficiency of moisture—as in a season of drought. But the results of the past three years' investigation indicate that a good crop of clover can be obtained on very poor soil with the aid of nitragin, provided the soil is drained (naturally or artificially), the season favourable, and there is a sufficient supply of mineral plant food in the soil.

There are, however, several rather serious difficulties in the way of the general introduction of nitragin. First, it must be used while still freshly prepared (the German manufacturers will not guarantee its vitality after it has been made six weeks), and, secondly, it must have been protected from strong light and kept at a temperature below 100° F.

We are of the opinion that any farmer might without purchasing nitragin obtain the same results by taking soil from a field that has grown a good crop of clover and sowing it over the poorer soil. The earth which comes from about the roots of clover contains the germs and, therefore, this method would be an actual inoculation of the poorer soil. This plan has worked most successfully with several experimenters, in both Europe and America. Another plan would be to pour cold water over the earth (previously placed in a barrel) from the rich clover land and after allowing the soil to settle, to pour off the supernatant water and soak in it the seed about to be sown.

PRELIMINARY REPORT UPON THE COMPOSITION AND PROPERTIES OF THE FAT IN 'FIRM' AND 'SOFT' PORK.

It has become a matter of great importance to Canadian farmers and those interested in the bacon export trade, to learn the cause or causes which produce 'soft'

or 'tender' pork, since such sells at a much lower price than 'firm' pork, both in the home and the English markets. With the view of furnishing useful information to pork producers, and, if possible, of solving this admittedly difficult problem, the chemical composition and physical character of the fat in these two classes of pork have been studied, it being considered that the results of such an examination would form a valuable basis or standard for reference in making further experiments. These latter would consist chiefly of feeding tests under various conditions (age, breed, exercise, &c.), and the analysis, chemical and physical, of the resulting pork.

On February 1, we received from the Wm. Davies Co., Limited, Toronto, two Wiltshire sides; the one marked 'firm,' and reported on as of excellent quality; the other marked 'soft,' and stated as of very inferior quality. The former weighed 46 pounds; the latter, 44 pounds.

Both were frozen when received, but, nevertheless, there was a most marked difference in the relative hardness of the two sides. As the sides thawed (at the temperature of the laboratory, about 70° F.) this difference—which was ascertained or measured by the resistance of the fatty portions to pressure by the finger—became still more pronounced. This was further evinced (February 2) in raising the ham by lifting as the sides lay on the table; the 'firm' remained fairly straight, whereas, the 'soft' doubled over. The relative softness is also shown in the accompanying photograph, the sides having been suspended the night previous. It illustrates the amount of 'drag' caused by the weight of the sides, similarly suspended by hooks. The extent of the 'drag' in the 'soft' side is much the greater.

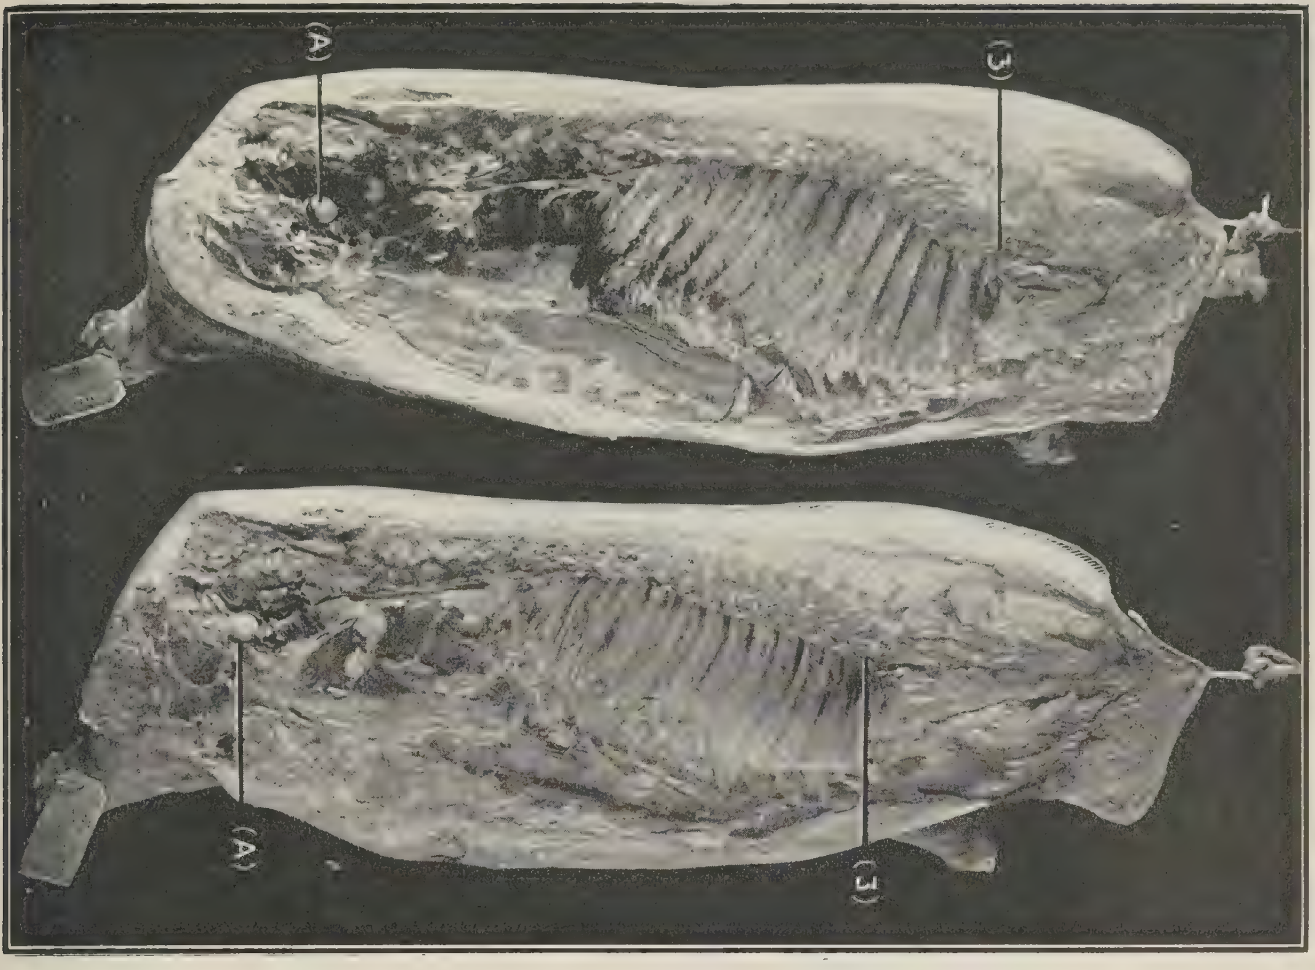
The samples of the fat for examination were obtained by first cutting the sides (*a*) immediately in front of the thigh joint (socket of the femur in the pelvic arch), and (*b*) immediately in front of the first rib, and then taking the fatty tissue at each of these sections. Those taken at (*a*) are designated in the following tables as 'ham'; those at (*b*) as 'shoulder' (see photo). The precaution of confining the place or area from which the fat was taken was made necessary from the fact that it has been stated that the fat varies considerably in composition, according to its position in the animal. Care was exercised in the preparation of the sample for analysis, to dissect out and reject all muscular tissue, blood vessels, &c.

Though the 'soft' side was somewhat the lighter of the two, its proportion of adipose tissue (fat) to muscle (lean) was the greater (see photo).

In determining the composition of the fat of the two sides, the following estimations were made: water, nitrogen (from which the amount of tissue other than fat was calculated), fat (which was obtained by difference), and the amount of olein and palmitin and stearin. The amount of salt present was also determined. Table 1 sets forth the results obtained :—

TABLE NO. 1.—*Composition of Fatty Tissue in 'Firm' and 'Soft' Bacon.*

—	Firm.		Soft.	
	Ham.	Shoulder.	Ham.	Shoulder.
Water	15·56	6·53	12·50	2·67
Salt	2·73	1·12	1·84	·48
Nitrogen	·504	·285	·243	·142
Fibre (Nitrogenous tissue)	3·15	1·78	1·52	·89
Fat, by difference	78·56	90·57	84·27	95·96
Olein in bacon	50·05	58·33	66·37	76·94
Palmitin and stearin in bacon	28·51	52·24	17·90	19·02



Soft Pork Investigation, showing Firm and Soft Sides.

Experiments with Nitragin; Clover Inoculated and Untreated, Second Year's Growth.

From the foregoing data we may notice several very important differences in the composition of the bacons. These differences are discussed in the following paragraphs:

1. It is to be observed that the percentage of water in the fatty tissue of the 'firm' is greater than in the fatty tissue of the corresponding part of the 'soft' bacon.

2. Also, that the percentage of tissue other than fat, that is, of a nitrogenous nature, was also greater in the 'firm' than in the 'soft.' This falls into line with the results stated in the preceding paragraph, since the water for the most part is contained in or held by the nitrogenous tissue. This would indicate, I think, that the walls of the cells containing the fat proper are thicker in the 'firm' than in the 'soft' or 'tender' bacon.

3 Further, it is to be noticed that the amounts of salt present are also larger in the 'firm' than in the 'soft' bacon. This is accounted for by the assumption that the salt, like the water, is held by the nitrogenous tissue to a greater extent than in the fat.

4. The percentages of fat are, from a consideration of the foregoing statements, necessarily greater in the 'soft' than in the 'firm' bacon.

5. The fat proper consists of olein, fluid at ordinary temperatures, and palmitin and stearin, solid at ordinary temperatures. The data show that the percentage of olein is much greater in the 'soft' than in the 'firm' bacon, while as a natural consequence the percentages of palmitin and stearin are greater in the 'firm' than in the 'soft' bacon. These facts furnish the cause of the greater softness in the 'soft' or 'tender' bacon.

COMPOSITION OF THE FAT.

In order to obtain a fuller knowledge of the composition of the fat proper in the 'firm' and the 'soft' bacons, the fatty tissue was rendered and the pure fat filtered off. The analysis of these fats furnished the data in Table No. 2.

TABLE NO. 2.—*Composition of Fat from 'Firm' and 'Soft' Bacon.*

—	Firm.		Soft.	
	Ham.	Shoulder.	Ham.	Shoulder.
Olein (calculated)	63·71	64·40	79·95	80·18
Palmitin and stearin	36·29	35·60	20·05	19·82
Ratio of palmitin and stearin to olein	1—1·76	1—1·80	1—3·99	1—4·02

These figures show very clearly that the fat of the 'soft' bacon contains a much larger percentage of olein than that of the 'firm' bacon, with a corresponding decrease in the percentage of palmitin and stearin.

They also make evident that no great difference in the composition of the fat taken from the ham and from the shoulder of the 'firm' bacon exist, and that the same statement regarding the fat of the ham and shoulder of the 'soft' bacon also holds true.

PHYSICIAL AND CHEMICAL CONSTANTS OF FAT FROM 'FIRM' AND 'SOFT' BACON.

Table No. 3 sets forth certain determinations that were made upon the pure, filtered fat. These are of considerable importance, since, though of a strictly scientific character, they allow us to make deductions easily understood regarding the nature of the fats :

TABLE No. 3.—Physical and Chemical Constants of Fat from 'Firm' and 'Soft' Bacon.

—	Firm.		Soft.	
	Ham.	Shoulder.	Ham.	Shoulder.
Melting point	37·6°C.	37·75°C.	27·4°C.	28·2°C.
Spec. gravity at 96°C	·8668	·8859	·8678	·8740
Spec. gravity at 100°F	·9009	·8980	·8970	·8988
Sapon. equivalent	285·3	282·3	287·3	286·0
Reichert number	·408	·714	·408	·663
Iodine absorbed	55·3	55·9	69·4	69·6

1. The melting point of the fat from the 'soft' bacon is practically 10° Centigrade lower than that of the 'firm' bacon.

2. The specific gravities in both series are so close that it is not possible to use this constant as a means of differentiation or for deducing therefrom any information respecting the relative composition of the fats.

3. The saponification equivalent likewise appears to be of little value in the diagnosis.

4. The Reichert number shows the practical absence of volatile fatty acids in both series, though there is an indication of larger traces of the presence of such in the shoulder fat than in that of the ham.

5. The 'Iodine absorbed' is of great value in this investigation. From it may be calculated the percentage of olein or liquid fat present in a fat. The data here presented clearly demonstrate the larger amount of olein in the 'soft' fat, a fact that gives the explanation for the greater softness or tenderness of the 'soft' bacon.

On the completion of the work recorded above, it was deemed advisable to institute a series of feeding tests upon the Central Farm, to be followed by a similar examination in the laboratory of the pork produced. Such a series (employing nearly 200 pigs) was commenced in the month of May, and is still in progress. All the pigs were between one and two months old when the experiment begun. The scheme of rations used for these pigs was drawn up by Mr. Grisdale, the Agriculturist, who has the control and management of the investigation outside the work done by the Chemical Division.

Already some seventy carcasses of these pigs have been submitted to chemical and physical examination—a work which has consumed more than four months time of the chemical staff. If, as we hope, the investigation proceeds satisfactorily, the data will be completed by April, 1900, when it is expected they will be collected and published, together with deductions therefrom, in bulletin form. Such an extensive trial should furnish us with results from which deductions of value can be made concerning the causes

producing 'soft' pork. The effects of food, as regards character and quantity, of exercise, &c., &c., upon the quality of the pork produced will, it is expected, be brought out, enabling us to furnish information that will be of service to those raising and feeding pigs.

At the outset of the experiment above referred to, it was thought well to ascertain the character of the fat in very young pigs, so that we might have data respecting age and immaturity as affecting the quality of the bacon. Accordingly, before the special feeding was begun, four small pigs were slaughtered and their fat examined in the laboratory. The dressed weights of the pigs ranged from 23 to 42 pounds. Inspection at the factory showed all to be more or less soft. The proportion of olein to palmitin and stearin in the fat of these pigs is given in the subjoined table :—

—	A.	B.	C.	D.
Olein	90·6	86·9	83·3	73·3
Palmitin and stearin	9·4	13·1	16·7	26·7
Ratio of palmitin and stearin to olein	1:9·6	1:6·6	1:5·0	1:2·7

Though the percentages of olein are seen to vary considerably, they are all sufficiently high to characterize the bacon as soft, thus corroborating the expert's opinion.

The above data are probably insufficient to base any final conclusion upon, yet they appear to indicate that age and weight—or perhaps rather immaturity or lack of 'ripeness'—are factors having a marked effect upon the character of the fat. Further work may show that the percentage of the olein decreases as the pigs grow and if such be the case, one of the causes of softness, at least, will have been discovered. The series of experiments now in progress will furnish data on this important feature of the problem.

WELL WATERS FROM FARM HOMESTEADS.

It is gratifying to be able to report that among the waters received this year for analysis a much larger percentage of good samples occurs than heretofore. The immediate relationship between an unpolluted, wholesome water supply and good health and thrift among cattle is one, however, that still needs emphasizing in many parts of the Dominion. It seems more than probable to the writer that many deaths among horses and stock, generally reported as due to obscure and apparently unknown causes, might be traced to the continued drinking of contaminated water, for such, apart from disease germs they may harbour, may, and often do, contain compounds (derived from certain chemical changes that take place in the organic matter of the excrementitious refuse present) possessing well-marked poisonous properties. The value of the abundance of pure water for the farmer and dairyman can scarcely be over-estimated. If this were more widely recognized, greater care would be exercised in guarding the well against the infiltration of noxious materials.

Respecting the purification of waters largely charged with saline matter, such as common salt, sulphates of soda, lime, and magnesia, we have to say that no system of filtration or precipitation will be found altogether effective. Recourse must be had to distillation. Stills for household purposes are now manufactured that can be used on the kitchen stove, and which require but very little attention. Sufficient water for drinking and culinary purposes, free from all soluble saline matter, may by these means be readily and cheaply obtained.

REPORT

OF THE

ENTOMOLOGIST AND BOTANIST

(JAMES FLETCHER, LL.D., F.L.S., F.R.S.C.)

1899.

DR. WM. SAUNDERS,
Director of Dominion Experimental Farms,
Ottawa.

SIR,—I have the honour to hand you herewith a report on some of the more important subjects which have been brought officially under my notice during the past season. There is, as in previous years, and as must always be the case, a vast amount of material accumulating in the Division which cannot be mentioned in the annual report, but which is frequently of use in answering correspondents and explaining to visitors the work of the Division.

Since the appointment of Mr. Arthur Gibson as a new assistant, in April last, many specimens have been secured for permanent exhibition in the museum. Exhibition cases in which the commonest injurious and beneficial insects can be shown have been a great desideratum here, a want which is now being filled as quickly as possible. Several new cases have been secured during the summer, but when the accumulated material has been arranged even these will not be sufficient to display all the specimens, and other cases are now being made.

The experiments in growing grasses and fodder plants have been continued and, as in the past, have proved of great interest to all visiting farmers. The Awnless or Smooth Brome Grass, which since 1887 I have taken great pains to introduce and distribute through the north-western provinces, still continues to give the greatest satisfaction to all who have tried it. It is a heavy producer of excellent fodder and hay, is succulent, appears early in spring and lasts late into the autumn. It is a free-grower, thriving both on light sandy soils and in rich low bottoms. Owing to its vigour and free growth, it has been found useful for holding alluvial flats liable to flooding and also as a binder of drifting sand. Some two or three years ago a sample of seed was sent to Mr. R. J. Bouteiller, Superintendent of Sable Island, off the coast of Nova Scotia, to whom it has given much satisfaction. He reported on it last year as follows :—'The Awnless Brome Grass seed was planted about the 20th May, and I mowed a heavy crop in August, much of it headed out. I am much pleased with it and believe it will be a success.' During the past summer Major F. Gourdeau, the Deputy Minister of Marine and Fisheries wrote as follows :—'Referring to the Awnless Brome Grass, of which you supplied seed to Sable Island, I beg to inform you that a letter has been received from the Superintendent of the island, in which he states that the plot of this grass is ahead of anything else, and measured on the 27th June between 3 or 4 feet and more in height, while timothy in just as good ground was a little over half of that.'

Awnless BromeGrass has also given tolerable satisfaction upon alkali patches in the west, succeeding better than all other varieties tried.

Subjects requiring special attention since I last reported were the following :—

The Hessian Fly.—A serious outbreak in Manitoba.

The Rocky Mountain Locust.—This insect again appeared in some numbers in southern Manitoba, but was not the cause of an appreciable diminution in the crops. The exceptionally wet and late season in Manitoba during the past summer was unfavourable for its early development and spread, and the farmers, having been stirred up to an appreciation of the danger of allowing this insect to remain undisturbed, ploughed down the greater part of the stubbles this autumn, thus burying the eggs too deeply for the young to emerge next spring.

The Destructive Pea Aphis.—One of the most notable outbreaks of the year was by a plant-louse which has been given the above name but which before this year was unknown.

Root Maggots.—Some experiments against these destructive enemies of the gardener were tried last season with many different substances, but so far without very satisfactory results. Mixtures containing some form of carbolic acid were most useful.

The Diamond-back Moth (*Plutella cruciferarum*, Zell.).—Late in the autumn there was in eastern Ontario a widespread and severe attack upon cabbage of various kinds, rape, and turnips, by this insect, which has been well known for many years as an occasional pest of these plants, and was fully treated of, and figured, in my report for 1890. In *Farm Insects*, by John Curtis, 1860, the same insect is described and well figured as the Turnip Diamond-back Moth.

The Asparagus Beetles.—Two new enemies of the gardener have appeared in Canada for the first time this year, the two Asparagus Beetles. These are treated of at some length later on.

Fig. 1.—The Forest Tent Caterpillar.

Tent Caterpillars.—Orchard and shade trees were again this year seriously injured throughout the greater part of Ontario and Quebec by the caterpillars of the two common species of Tent Caterpillars. Nothing new can be added as to remedies; these consist of the collection of eggs in winter, the destruction of the nests and clusters of young caterpillars in spring, and last, but most important, the spraying of trees with poisonous mixtures as soon as possible after the hatching of the eggs. The last operation, when performed carefully, is a never-failing remedy.

Bark-lice.—The San José Scale and several other allied species of scale-insects have naturally been the subject of much correspondence. Thorough experiments are now being carried out by specialists in all parts of North America with the hope of discovering a practical remedy. Several materials have given good results which with ordinary insects might be considered all-sufficient remedies, but with the San José Scale it seems inadvisable to recommend under the existing laws which have been passed by the Federal Government and those of Ontario and British Columbia that fruit growers themselves, should be allowed to treat their trees with any of the materials which, up to the present, have been claimed to be 'sure remedies,' such as pure kerosene, the same mechanically mixed with water, and crude petroleum.

The Apricot Scale (*Lecanium armeniacum*, Craw).—Another scale insect from California, which in some way has been introduced into the Eastern States, and is spreading there to some extent, has been found in two or three orchards at Sherbrooke, Que.

THE RASPBERRY WEB-WORM.—A local but interesting attack by a new enemy to cultivated raspberries was reported from St. John, N.B., last year, and has been worked up during the past season.

THE CRANBERRY LOOPER (*Caterva catenaria*, Cram.).—A new attack of some severity upon strawberries was by the common 'Cranberry Worm,' which was reported by Mr. George Bonner, of Point Aconi, Cape Breton, N.S.

THE PEA MOTH (*Semasia nigricana*, Steph.) is still much complained of, particularly in the Maritime Provinces, as shown by the following letter :—

'CLIFTON (King's Co.), N.B., December 19.—I have not made any recorded observations, but think this insect was not quite so destructive last season as usual. It has, however, come to be such a matter of course with us, that we take its ravages quite philosophically and pick the caterpillars out of our peas for the table; when too bad, we throw the whole mess to the pigs or cows. This insect has been injurious here for a period beyond my recollection, some 50 years.'—J. W. WETMORE.

THE CARROT RUST-FLY (*Psila rosæ*, Fab.) continues to be a troublesome pest of carrots in the province of New Brunswick. Mr. J. E. Wetmore, of Clifton, N.B., writes :—'Of late years we have about abandoned the culture of the tender varieties on account of its depredations. It does not trouble the hardier varieties here apparently, for we can get full crops of the white carrots when the orange ones are a complete failure in the same field.'

In Prince Edward Island, Father Burke reports widespread injury by plant-lice upon carrots.

THE SPRUCE GALL-LOUSE (*Chermes abietis*, Linn.)—A cause of considerable inquiry and anxiety among those interested in the manufacture of paper during the past year or two has been the Spruce Gall-louse. This insect is prevalent through a large part of Ontario, attacking the Black and Norway Spruces. In the Rocky Mountains, galls probably made by a different species were noticed in abundance on White Spruces at Banff, Alberta, and, on Vancouver Island, trees of the Menzies Spruce (*Picea sitchensis*, Carr.) in certain places in the forests, were much disfigured by another species of Chermes, probably *C. sibirica*, Cholodk., which forms large galls, sometimes two inches in length by nearly one in diameter. These were not found at all on the Douglas Spruce.

THE BLACK VIOLET APHIS.—An infestation of greenhouses not previously complained of in Canada by the above insect occurred in Toronto, and is treated of later in this report.

THE GREENHOUSE LEAF-TYER is also a new pest treated of hereafter.

THE CARPET BEETLE OR 'BUFFALO MOTH' (*Anthrenus scrophulariæ*, Linn.).—This troublesome pest of the housekeeper seems to be spreading and becoming more destructive year by year. During last spring a few specimens were taken out of doors at Ottawa on the flowers of Currants and Spiræas. Beetles were also sent from Bewdley (Northumberland Co, Ont.) which had been found by Mr. T. W. Ramm, in the folds of a cloth left hanging in an apple tree during winter.

Correspondence.—From November 30, 1898, to November 30, 1899, the number of letters received by the Division was 2,495, and of letters sent 2,320.

Meetings attended.—Meetings of farmers, dairymen and fruit growers have been attended at the following places :—January 10 and 11, at Kingston; 27, at St. Catharines, February 3, at Hemmingford, Que.; 10, at North Gower, Ont.; March 10, at Merivale, Ont.,

17, at Montreal; April 3, at Napanee, Ont.; 4, Brampton; 5, Oakville; 6, Hamilton; 7 St. Catharines; and three series of meetings in Manitoba, the North-west Territories and British Columbia are reported on at the end of this report.

Acknowledgments.—As in previous years, I am under great obligations to many correspondents, to practical farmers, who have much aided the work of the Division by making observations and sending in prompt reports on the occurrence of injurious insects and weeds, and to scientific experts in Canada and abroad. I must particularly mention in this connection Prof. John Macoun, of Ottawa, for assistance on many occasions, and also Dr. L. O. Howard, United States Entomologist, of Washington, D.C., and Dr. J. B. Smith, of New Brunswick, N.J., for frequent assistance in the identification of insects and for the use of electrotypes and magic lantern slides.

In conclusion I have much pleasure in expressing my appreciation of the enlarged opportunities for doing good work in the Division entrusted to my care, which have been granted me during the past year.

Mr. Arthur Gibson, of Toronto, was appointed as an extra assistant on April 1 last, and has shown great assiduity and care in all matters entrusted to him. Mr. J. A. Guignard, B.A., the Assistant Entomologist and Botanist, continues to help me in all branches of the work of the Division, and as heretofore has done much to bring the Division of Entomology and Botany to such degree of efficiency as it has attained.

I have the honour to be, sir,

Your obedient servant,

JAMES FLETCHER,

Entomologist and Botanist.

CEREAL CROPS.

Complaints of injury to the wheat crop by insects during 1899 were few, with the exception of a new and severe outbreak of the Hessian Fly in Manitoba, a rather serious occurrence of the same insect in Western Ontario, and a slight one in Prince Edward Island.

In the November *Crop Report* (Ontario Bureau of Industries) it is stated:—'There has been a notable absence of insect pests. There are few complaints of insect pests except that Hessian Fly, Jointworm and Wireworm have done some damage.' 'Alberton, P.E.I., October 31.—Seldom has Prince Edward Island garnered a more satisfactory all round harvest than this year. Hay is bursting the mows, the granaries are filled with golden grain, and although in some sections potatoes are not an average crop, on the whole, we rejoice in an excellent yield of roots.'—Revd. A. E. Burke.

'Pleasant Grove, P.E.I.—The wheat crop on the whole is a good one; some fields were damaged by what we call 'black neck,' said by some to be the rust. Attacks by the Hessian Fly were not common, a few plants being injured, but we have had a considerable quantity of Wheat Midge on the Island this year.'—E. Wyatt.

Barley was slightly injured by Hessian Fly in Manitoba, and oats and corn in Ontario to some extent by grasshoppers. The two most serious outbreaks of the season upon cereals were by Hessian Fly in Manitoba and in Western Ontario, and by a new enemy of the pea, the Destructive Pea Aphis, which did great damage to field peas from the Maritime Provinces to Western Ontario in Canada, and extended right down to the Southern States in the Union. That old enemy, the Pea Weevil, was also more than usually destructive and abundant during the season of 1899.

THE HESSIAN FLY

(*Cecidomyia destructor*, Say).

Fig. 2.—The Hessian Fly—enlarged and natural size.

Complaints of injury by the Hessian Fly during the past season were numerous to fall wheat in Ontario and to spring wheat in Manitoba. Wheat was injured in many parts of Manitoba, but chiefly in the Red River valley. The most western occurrence reported to me (with specimens) was from Moose Jaw, in the North-west Territories. At the request of some of my correspondents for public advice as to the best means of preventing future loss, articles were prepared for publication in the *Farmer's Advocate* (September 15) and the *North-west Farmer* (September 20), both excellent agricultural journals, widely circulated and read by farmers, in which the chief points in the life history of the insect were given and suggestions made as to the best known remedies.

The following extracts from some of the large correspondence on the matter will show the extent and nature of the outbreak. The first reports and specimens from Manitoba were received from Mr. Hugh McKellar, Chief Clerk of the Provincial Department of Agriculture.

'Delmer (Norfolk Co.), Ont., August 8.—In view of the immense damage done by the Hessian Fly to the wheat crop in this and in many other localities throughout the

province, farmers are very much interested in the matter and would like to know something of the habits of this insect—whether it is likely to assert itself in next year's crop, whether the discontinuance of wheat growing for a season would be necessary to exterminate it, or whether such omission would be of any value in eliminating the pest, &c., &c. Any information you could give us would be very gratefully received, especially at this juncture—the eve of another seeding.'

'Delmer, September 13.—In South Oxford the fly was very injurious, destroying fully one-half of the fall wheat remaining, after an unusually severe 'winter killing'—there was scarcely a wheat field that was not injured more or less; the earlier sown suffered most. In North Oxford damage was much less, in West Brant, also much less, ditto in West Norfolk, in East Elgin middling severe, quite severe in East Middlesex; and again, in North and West Middlesex not so severe.'—CHAS. BRADBURN.

'Winnipeg Man., August 26.—Herewith I am sending you specimens of an insect that has done considerable damage on the farm of Mr. James Little, Stonewall. The specimens were forwarded by Mr. Ira Stratton, of Stonewall, who says that about one-quarter of Mr. Little's wheat has been cut down by these insects. Would you kindly let us have any information at your command regarding this pest, and what measures should be adopted to prevent its recurrence next year?'—HUGH MCKELLAR, *Chief Clerk, Dept. Agriculture.*

'Macdonald, Man., August 26.—I notice since starting to cut my wheat that quite a lot of the straw is broken just above the second joint, although the heads seem to be well filled; of course the sap is not altogether stopped as the straw is not broken completely off. I find on examining it that there is a single maggot or worm in a brown shell, between the leaf and stem just above the joint, that has caused the injury. Can you tell me what it is and if it is likely to be worse another year? There is from 1 to 7 or 8 per cent of the straw affected with it.'—HENRY KIRKWOOD.

'Portage la Prairie. Man., August 28.—Inclosed find wheat joints which I have cut from my field. The wheat is bent down just above the joint. I find by opening the straw that there is an insect on the upper side of the joint. The grain in the head appears to be all right, but the straw and head are not as large as the balance that is standing. My heavy wheat does not appear to have been affected. Would you kindly let me know through the *Nor-west Farmer* what it is, as I presume there are other fields throughout the province affected the same way?'—CHAS. CUTHBERT.

'Winnipeg, August 29.—At several points throughout the province I have noticed this year in the wheat fields that a greater or less proportion of the straws appear to break about the first joint from the ground, and, where this is very bad, it gives almost the appearance of their having been broken down by hail, except that most of the straws seem to lean in one direction as though they had gone down under pressure of high winds from one quarter. I am told by some parties that a little worm about $\frac{1}{4}$ of an inch long is found in the straw, at the first joint. The appearance of the head is entirely different from what we call "dead heads" as the grain is maturing in the heads, some of them still being comparatively green, although I think in every case the grain will be shrivelled, and the heads seem to be shorter and smaller than the average heads in the field. I saw two fields of this out at Melita a little while ago, and yesterday at Otterburn saw a great deal of it, and I understand from the farmers at Emerson, that it is very prevalent throughout that district. I was also speaking to a man from Plum Coulee, who told me he had to set his binder much lower than usual in order to avoid cutting off the heads that were broken down, and I am inclined to think that this trouble, whatever it is, is very prevalent throughout southern Manitoba.'

"Winnipeg, Oct. 11.—I fancy the damage done by the Hessian Fly has been pretty serious in some localities, but, as people were not acquainted with the insect or were not looking for it, not many noticed it; perhaps, too, they attributed the shortage to a wrong cause. I understand that its attacks were very bad in the Stonewall, Carman and Niverville districts."—G. H. GREIG, of *The Farmer's Advocate.*

'Winnipeg, Oct. 3.—In response to your request for information on the Hessian Fly in this province, by Mr. McKellar's instructions, I made an excursion to Stonewall on Friday and Saturday last. There is no doubt whatever that the fly is all through

the wheat-growing country around Stonewall and Balmoral—every farm I inspected had it. I found puparia in every wheat and barley field I entered, and in every stack of unthreshed wheat looked at. I was able to examine the screenings from one threshing place (on the farm of Mr. J. Little) and here there were puparia in abundance. The first place visited was the farm of Mr. J. McEwen, where there was a piece of breaking very bad with the fly. Mr. McEwen estimates the damage at one-third of the crop, and I am sure the estimate is a careful one. The next place visited was Mr. Jas. Little's. It was from this farm that the specimens were sent to you last month. The damage here was quite as great as on the last place, but in this case the land bore a crop of wheat last year. It was on this farm that I examined the screenings from the thresher. Mr. Martin Shepley estimates the damage done to his summer-fallow at one-fourth or perhaps as much as one-third. I have mentioned these three farms because they are the only cases in which I was able to see the farmers and discuss the question with them. As to barley I could secure no estimate of the damage done. No barley had been threshed, and there is not the same interest in the barley crop as in wheat. I did not find the puparia so numerous in barley fields as in wheat fields. The puparia were almost invariably above the second joint, usually singly, though sometimes in twos and threes. I collected a number of specimens of which I send you a few in case you wish to breed the parasites.

'Summer-fallow and breaking suffered quite as badly and as generally as land cropped last year. Fallow and breaking are naturally the earliest sown, as they are soonest in condition for seeding. The weather during seeding was very cold and backward, and continued so up to the 10th June, after which the most perfect conditions for growth prevailed. I may also quote the statement of Mr. J. Little that the wheat which was earliest cut was less broken down than that cut later. In reply to a further question, he said he did not know whether it was less *damaged*, but it was certainly less broken down. Mr. J. McEwen stated that greener portions of a field were less broken down than riper ones. From this I would point out that the amount of damage was estimated generally from the state of the crop before threshing, that green or under-ripe grain does not break off so readily, and that a crop cut a shade green would not show the full amount of damage done.'—MELVIN BARTLETT, *Dept. Agriculture.*

'Buffalo Lake, Moose Jaw, Assa., Aug. 30.—When I wrote you some three or four weeks ago with regard to the wheat pest, I had not observed any indications of it. Since then it has become quite evident. I learn from a neighbour adjoining me that he had it last year. At present there are quite a number of heads through my crop and a very considerable number in my near neighbour's. It seems especially bad on the outside of the field; where he was cutting wheat 2 or 3 days ago, the outside 10 or 15 feet was very materially damaged. It seemed to attack the maturer heads, not troubling the greener grain much.'—G. S. TUXFORD.

'Emerson, Man., Sept. 1.—I am enclosing to you some samples of wheat straws injured by the insect referred to you some days ago by Mr. Geo. Greig of the *Farmer's Advocate*, Winnipeg. You will find them located immediately above the joint first from the ground. Kindly examine and let us know the name, and likelihood of recurrence another year, remedy if any, and any information you deem of use. This pest is more or less found all over the province, and is estimated to have done as much damage in some places as to reduce the yield 20 per cent.'—W. W. FRASER.

'Winnipeg, Sept. 1.—We enclose sample of straw from Winkler Station, where it has drawn attention. Is it the Hessian Fly?'—RICHARD WAUGH, *The Nor-West Farmer.*

'Winnipeg, Sept. 1.—Enclosed find a few stems of wheat straw cut at ground and fallen in crop so as to be missed by the binder. In each straw is an insect, the cause of fall. About one in a hundred of the stems was so affected. What is it and how can it be treated?'

'Holland, Man., October 4.—In every field I have looked (that is in Manitoba), I have found traces of the Hessian Fly. I know of no other insect doing the farmers any injury this season.'—F. D. BLAKELY, of *The Nor-West Farmer.*

'Balmoral, Man.—I am sending you under separate cover an insect in pieces of wheat straw. It is found at the joint nearest the ground. Just above this joint

it eats its way through the stalk and escapes. The straw bends or breaks at this place, leaving the straw as if fowls had pulled it down. One man told me his wheat would not be more than half a crop owing to the work of this insect. Would you kindly let me know what it is? It was not noticed until cutting commenced'.—R. W. NEILL, M.D.

'Pilot Mound, Man.—A considerable quantity of the wheat is breaking down badly at the second joint. I was attributing the cause to the straw being weak, owing to rust and showery weather making it softer than usual. I have examined some of the broken straws and found one containing a chrysalis, which I enclose. I hope the western wheat fields are not going to be troubled with weevil or any kindred pest. The wheat crop in this district is practically all in stook. Several were thinking that it is always better to begin on the green side as a very severe wind storm seemed to have broken the straw down.'—D. A. STEWART.

'Portage la Prairie, Man.—As to the extent of the damage by the Hessian Fly, it is very uncertain, some districts were more seriously affected than others. We had several light hailstorms here and there, and many farmers thought they were slightly damaged, but I now think that the damage was caused by the Hessian Fly. I find that the yield is not up to the expectations of the farmers, more especially in the older districts, and I am convinced that it was the Hessian Fly that reduced the yield. But we have been blessed with the most uniform good crop I have ever seen in the province, and hence the slight damage done is not seriously felt. The weather has been, and is yet, simply grand. I found in gathering these specimens I send, that they were more plentiful in late grain than in earlier, also the last heads to come out were the most affected.'—CHARLES BRAITHWAITE.

As stated above, last season is the first in which the Hessian Fly is known to have done harm to crops in Manitoba, and many farmers did not recognize the insect until the matter was brought before them by discussion in the daily journals and agricultural press. With a view to gathering as much information as possible about the occurrence and extent of injury, a series of questions was submitted by the *Farmer's Advocate* to its readers, and answers were received from many of them. Some of these answers were published in the issue of December 5, from which it would appear that the loss, according to locality, was from 5 to 25 per cent of the crop, and that the attack was general, irrespective of the nature and condition of the soil, or the time of seeding. Nevertheless farmers in different localities held strong opinions that there were decided differences, some stating that early sown grain was exempt from attack, while others thought the opposite. Mr. W. R. Graham, Superintendent of the Stony Mountain Penitentiary farm, Manitoba, stated to me on October 4, 1899, that the Hessian Fly did not attack his early sown wheat at all, and he thought this was general throughout his neighbourhood, that in 1899 early sown wheat was much less attacked than that which was sown late and held back by the late season.

In answer to the questions in the *Farmer's Advocate*, Mr. R. W. Greig, of Otterburn, reports that late-growing grain suffered most, although, in some cases, that which was sown very early was injured more than some of that which was put in late. Mr. H. O. Ayearst, St. Paul's municipality, reports wheat on new land as 'badly damaged, at least 25 per cent of the crop; no injury on old land, new land only being injured.' On the other hand, Mr. S. R. Henderson, of Kildonan, reports it to have been 'worst on old land that had been summer-fallowed, with surface cultivation in the spring, and sown early.' Mr. Robert Fisher, of Springfield, says: 'I could see no difference on old land or new, fallow or stubble, fall or spring ploughing, or in early or late sowing, though none of our sowing was very early. My own crop was seriously injured by the fly, 8 to 18 per cent of the whole crop being destroyed.'

The extent of injury was doubtless due to the condition of the wheat plant at the time the females were laying their eggs. The injury by the maggots of the summer brood is, as a rule, at the lowest joints of the stems, and, as upon hatching the young maggots work their way down to the base of the leaf upon which the eggs were laid, it would indicate that the plants which showed injury were those of which the stems were just shooting up at the time the eggs were laid. At the same time, it must be remem-

bered that there is on spring wheat in spring an early attack at the roots similar to that on fall wheat in autumn, by which very large numbers of wheat plants are destroyed without making stems at all. This attack is, as a rule, not noticed by farmers, because the plants which are left living, stool out more and fill up the gaps.

In a field which I had under constant observation during the summer of 1890, many plants were entirely killed by the spring attack, and others bore only a single weakly stem, most of the shoots having been destroyed; but, from the stooling of the uninjured plants, the general appearance of the field was that of a fair crop, and none of the straws could be found containing puparia, showing that all the eggs were laid before the plants began to shoot. Without close observation this attack would have been overlooked and would not, in all likelihood, have been noticed by farmers. Nevertheless the puparia of the insects which had done the harm, were still in the fields to emerge later and carry on the injury. This same state of affairs may have been the case in Manitoba last year, and much injury then done which was unnoticed. Although not detected, the Hessian Fly must certainly have been present in Manitoba in considerable numbers last year for eggs to have been laid over such a wide area. I have no doubt from an examination of specimens collected in various parts of Manitoba last autumn, that in that province there is only one brood of the Hessian Fly. This insect confines itself in a remarkable degree to the wheat plant, and, although barley and rye are occasionally attacked, this is exceptional; the very rare occurrence of pupæ in timothy, which has been recorded, must be regarded as quite accidental. No fall grain of any kind is grown in Manitoba, and puparia formed in the straws last summer still (December 30, 1899) contain living larvæ in good condition.

Prof. F. M. Webster, the author of most valuable studies on wheat pests, has maintained for many years that the Hessian Fly would be found to be single brooded when a point sufficiently far north or south of its metropolis, or centre of distribution, was reached, the extremes either of cold or heat preventing the production of food in suitable condition for the second brood, the summer brood instead of emerging in autumn hibernating as flax seeds in the north and in the south remaining in a quiescent condition (æstivating) as flax-seeds during the hot dry period of the protracted southern summer.

This theory of the insect's power to adapt itself to varying conditions was explicitly set forth by Prof. Webster in Ohio Bulletin No. 51, 1893, and as late as March last the same author writes:—'As you know, I have always questioned the occurrence of a second brood of Hessian Fly so far north as North Dakota, but I have never had an opportunity to substantiate my position. I had hoped that you might settle this Hessian Fly problem, and put the question to rest once for all with respect to the number of broods. The insect certainly occurs in areas where there is no fall wheat, but an abundance of spring wheat, and it does not seem to me possible that it could survive in such localities if it were double-brooded, as there is nothing on which a fall brood could winter over, except the spring wheat stubble.'

The importance of exact knowledge as to the number of broods is seen to be very great when we come to a consideration of remedies. The severity of the attack during the past season and the interest which has been created in the subject, through the agricultural journals, added to the fact that the weather has been most propitious this year for autumn work, have induced farmers to make themselves acquainted with the natural history of the Hessian Fly, and to adopt the methods which experience has shown are the best: namely, to burn over the stubble when possible before ploughing, and, at any rate, to plough down deeply all stubble this autumn or before the season for the flies to appear next spring.

As Mr. Greig has stated in the *Farmer's Advocate* for October 20:—'Whether or not the stubble is burned off, the land should be carefully ploughed. Even with no Hessian Fly, careful ploughing is really one of the great essentials to a successful crop. The work cannot be too well done. Not only does good ploughing leave the land in better shape and kill more weeds, but it greatly reduces the amount of harrowing and after work necessary to get the land into the best condition for the seed; and no doubt grain that comes away vigorously and early, and makes rapid growth, has more chances of escaping this or any other pest.'

The following article was published in the *Farmers' Advocate* for September 15, 1899, and similar articles were prepared for the *Nor-West Farmer* and other Manitoban papers :—

THE HESSIAN FLY.

During the past season rather extensive injury has been wrought by that old-time enemy of the wheat-grower, the Hessian Fly. From Western Ontario comes intelligence of the worst attack upon fall wheat, and the question is asked by some farmers there, whether it would not be well to discontinue altogether for a season the cultivation of fall wheat. The most serious injury and the attack of by far the greatest importance as pointing to future possibilities of loss from the Hessian Fly is reported from the Province of Manitoba, by Mr. George H. Greig, the Manitoba editor of the *Farmer's Advocate.* Inquiries and specimens have been received from almost all parts of the province, and from as far west as Moose Jaw in the Territories. Correspondents estimate the loss at between 5 and 20 per cent. This, of course, is all in spring wheat, as in the west no grain is sown in the autumn.

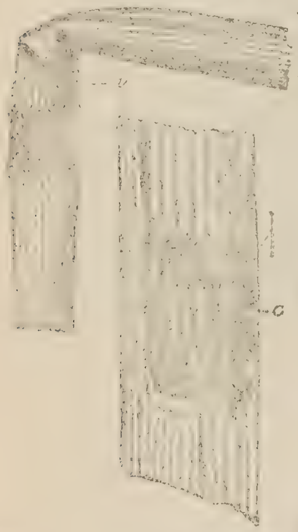

Fig. 3.—Hessian Fly: injured wheat-stem; three puparia enlarged.

The life history of the Hessian Fly is well known. The effects of the injurious work of the maggots on fall wheat can be recognized in the spring of the year by one or more dead shoots or whole plants in wheat fields. Upon examining these plants the characteristic pupa-cases, which resemble closely small elongated flax seeds, may be found in the crowns of the injured plants. Sometimes three or four specimens will occur beneath the leaf-sheaths of a single shoot. The flies from this brood emerge in the spring and lay their eggs upon the leaves of the shooting grain, and later, as at the present time in Manitoba, the same flax-seed-like pupa-cases described above and shown at Fig. 3 may be found above (as a rule, but occasionally higher), the first or second joints of the stems of barley, rye and wheat, where they lie between the base of the leaf-sheath and the stem, somewhat sunk in the tissues, so as to give the appearance of being actually inside the stem. During their growth the maggots have lived at the expense of the wheat plant, sucking the sap, so that the stems are weakened and frequently fall down, bending over just above the point of attack. This is well shown at Fig. 3*a*, and by it the presence of this enemy will probably be recognized by many Manitoba farmers who may have overlooked it in their crop. In Manitoba, it is most probably the case that there is only one brood of the Hessian Fly in the year, the winter being passed in the 'flax-seed' condition, for the most part in the stubble, but also to some extent in the straw which was harvested. Further south than Manitoba there are two distinct broods.

The perfect insect, a tiny blackish gnat, not expanding more than a quarter of an inch from tip to tip of its wings, appears in May and June and lays its eggs, which produce the summer stem-attacking brood. In Manitoba the flies from this brood do not emerge until the following spring, but in Ontario they appear in August and until about the middle of September, and the females lay their minute scarlet eggs upon the inside crease of the leaves of early-sown fall wheat. The young maggots, upon hatching, work their way down to the axils of the leaves, where the injury to the plant is done. Most of these maggots become full grown before winter sets in, and assume the 'flax-seed' condition.

Remedies—1. Late sowing.—With regard to fall wheat, the postponement of seeding until after the third week in September delays the appearance of the young plants above the ground until all the egg-laying flies of the second brood are dead. In cases where fall wheat has been sown in August and is already well up, it will be well this year, in such localities as the Hessian Fly is known to have been present, to feed off the young grain with sheep. In this way many of the eggs, it is claimed, are eaten with the leaves of the wheat. Care must be taken that the fields are not cropped too closely or too late in the season.

2. Burning refuse.—Many of the 'flax-seeds' of the summer brood are carried with the straw, and at threshing are dislodged and thrown down beneath the machine,

among the rubbish, or are left in the straw. All screenings and dust should therefore be destroyed carefully, and all straw should be either used during the winter or burnt before spring.

3. Fertilizers.—When it is known that a young crop of fall wheat has been injured by the Hessian Fly, it is a good plan to apply, the following spring, a light dressing of some quick-acting special fertilizer in order to invigorate the plants.

4. Treatment of stubble.—As the Hessian Fly is undoubtedly restricted in Manitoba to the summer straw-attacking brood, the remedy is simple, and, if persisted in, I cannot think that the Hessian Fly need ever become a serious menace to western wheat-growers. The insects passing the winter for the most part in the stubble and not appearing until the following spring, when there are growing wheat plants for the females to lay their eggs upon, if the stubble be burnt over or plowed down in autumn and the straw fed to stock or burnt at any time before the flies emerge in the spring, this dire enemy of the wheat-grower should be easily controlled.

It was to be expected, as stated in my last annual report (*Exp. Farm Report*, 1898, p. 174), that at no very distant date we might have trouble from the Hessian Fly in our western wheat fields, for Prof. Lugger has recorded that in the Red River valley, in Minnesota, where the conditions are similar to those of a large part of Manitoba, a large area of that state was infested in 1896, the damage in some places amounting to more than 25 per cent, and that on an average the farmers lost from 5 to 10 per cent of their entire wheat crop.—J. FLETCHER.

Fig. 4.—Hessian Fly: puparium containing six cocoons of *Polygnotus hiemalis* —enlarged.

Fig. 5.—*Bæotomus destructor*, female—enlarged.

One of the chief reasons why the Hessian Fly has not been very injurious in Minnesota since 1896 is, Prof. Lugger thinks, the abundance of parasites which appeared in 1897. A few of these friends of the farmer (*Polygnotus hiemalis*, Forbes) have been found in infested straws sent to me by Mr. W. W. Fraser from Emerson, Man. Three specimens of the most important parasite of the Hessian Fly, *Bæotomus (Merisus) destructor*, Say, were bred by Professor Lugger from straws sent to him by Mr. Chas. Braithwaite from Portage la Prairie. It is to be hoped that these parasites will increase largely in numbers. Unfortunately, however, Professor Lugger writes under date October 20, that in Minnesota 'Parasites of the Hessian Fly, are decidedly scarce this year. From 40 different places (about 75 infested straws from each) I have raised less than 25 parasites. Nearly all of them came from straw obtained from near Crookston, Polk Co., Minn. South of that place I have found none, north but a few.' Manitoba material received from Mr. Braithwaite contained three specimens of the females of *Bæotomus destructor*. On the other hand, in Prince Edward Island a much more satisfactory state of affairs may be reported; for, from a packet of infested straws from Mr. Wyatt received during 1898, no less than five different kinds of parasites were reared, viz:—*Bæotomus destructor*, *Eupelmus Allynii*, French, *Eupelmus*, n. sp., *Tetrastichus productus*, Riley, and *Entedon*, possibly *E. metallicus*, Nees. Cuts 3, 4, 5 & 6, used here have been kindly lent by

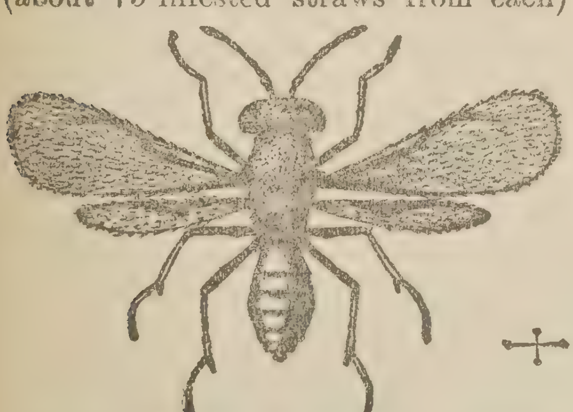

Fig. 6.—*Eupelmus Allynii*, male—enlarged.

Prof. Lugger. Reports from Prince Edward Island this year mention serious injury by Hessian Fly ; this is most probably owing to the increase in the numbers of these parasitic species.

THE DESTRUCTIVE PEA APHIS

(*Nectarophora destructor*, Jnsn.).

Attack.—Pale green plant-lice with legs darkened, particularly at the joints, honey tubes very long ; clustered in enormous numbers at the tips of the shoots, beneath the leaves, and sometimes over the whole plants of field peas, as well as upon the flowering Sweet Peas. These insects appear suddenly in large numbers and very soon kill the plants by sucking their sap. The winged specimens are rather large for aphides, being about one-eighth of an inch in length, with a wing expanse of nearly one-quarter of an inch.

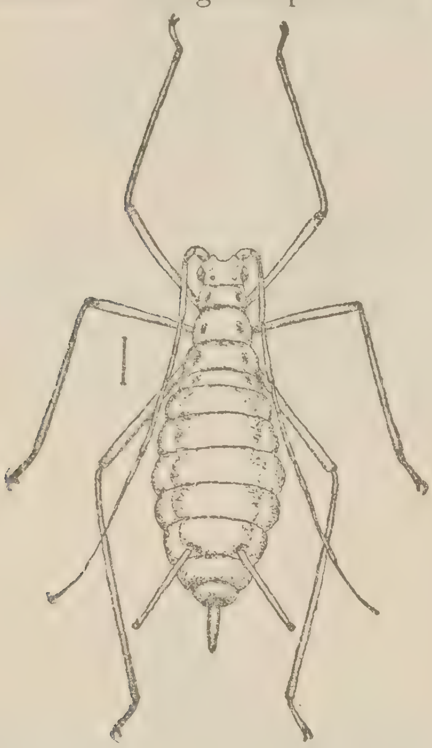

Fig. 7.—The Destructive Pea Aphis : wingless viviparous female—enlarged.

One of the most remarkable outbreaks of the year, which extended over a very wide area, was by a previously undescribed species of plant-louse. This was reported from various places in Canada from the Maritime Provinces to Western Ontario, even extending up into the sparsely settled country in the Nipissing District. It also occurred in destructive numbers in many parts of the United States ; Prof. Johnson, of Maryland, the describer of the species, who read a paper on the subject at the last meeting of the Association of Economic Entomologists, says:—

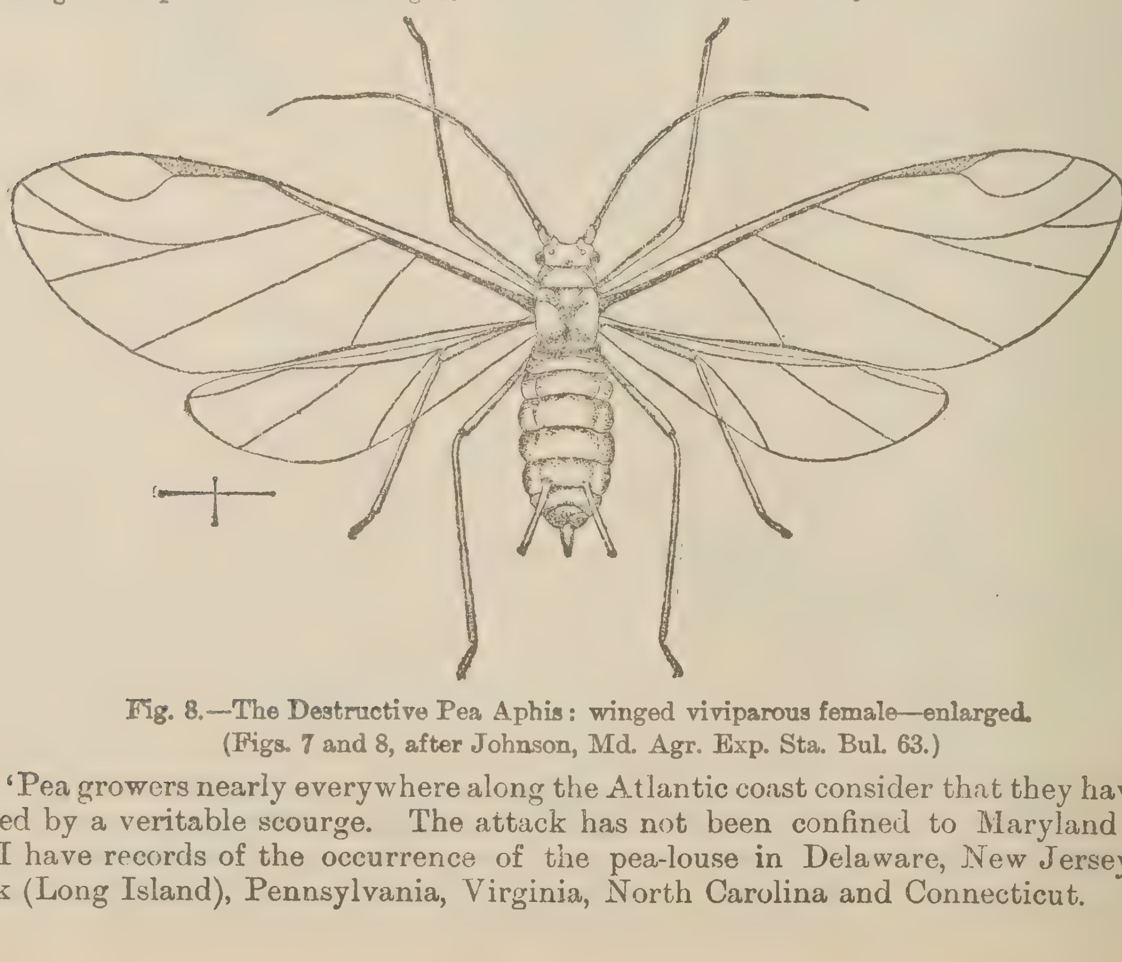

Fig. 8.—The Destructive Pea Aphis : winged viviparous female—enlarged. (Figs. 7 and 8, after Johnson, Md. Agr. Exp. Sta. Bul. 63.)

'Pea growers nearly everywhere along the Atlantic coast consider that they have been visited by a veritable scourge. The attack has not been confined to Maryland alone, but I have records of the occurrence of the pea-louse in Delaware, New Jersey, New York (Long Island), Pennsylvania, Virginia, North Carolina and Connecticut.

'The growing of peas in Maryland is a very important industry, and reliable conservative authorities place the loss this season at $3,000,000, the principal cause being the pea-louse. In many cases the destruction was complete, varying from mere garden patches to hundreds of acres.'

The Destructive Pea Aphis appeared in alarming numbers in the United States this year much earlier in the season than was the case in Canada, and consequently the loss to pea growers was greater, because in Canadian fields the seeds inside the pods in some instances had become fully formed before the Aphis appeared. By the end of May in Maryland many acres of peas were already destroyed, but in Canada it was not until the very end of July that the first complaints of injury began to be received.

The following extracts from some of the letters of correspondents will give an idea of the suddenness with which this insect appeared and the extent of its injuries :—

'Alberton, P.E.I., Oct. 31.—It appeared as if nature had striven this year to multiply aphides to infest every kind of plant. All the fruit trees were infested, the whole range of garden truck had its load, and out in the fields they so mutiplied on peas sown without grain as to flatten vigorous crops to the ground and completely ruin them. The rain prevented the kerosene emulsion from doing its work.'—Rev. A. E. Burke.

'New Minas (Kings Co.), N.S., July 29.—I observed to-day when walking through my peas, that there were swarms of active flies somewhat resembling house flies, only very shiny. (These were evidently Syrphus flies, the larvæ of which do such good service by feeding upon plant-lice, as stated further on.—J.F.) On looking closely, I found that the vines, including the young pods, were all covered with creeping insects. I send you some of these, and shall be glad to know anything you can tell me about them, for I fear that they will destroy the crop.'—Budd Bishop.

'Nappan (Cumberland Co.), N.S., August 8.—I send you samples of the work of the insect which is destroying our peas. I am very much afraid that it is going to ruin completely our experimental pea plots. These insects increase and spread with amazing rapidity. On Aug. 2, I went carefully over all the pea plots and noticed that there were a few of these insects distributed all over them. By the 6th they were in great numbers in spots all over the field, and now, two days later, they cover the whole vines, so that the whole crop will surely be ruined. The lice cluster upon, and completely hide the tender parts of the stalk, the blossoms and the under surfaces of the leaves. On account of their being mostly on the undersides of the leaves, it is hard to get at them with any kind of spray. This aphis seems to be very much like the one we sometimes have on plum trees, but it is now much more numerous than anything I have ever seen on plum trees, for these literally cover the whole field and they only take about 10 days from the time they first appear to suck the life out of the plants and leave white dead stalks. I am afraid this is a very serious matter for our pea crop.'—R. Robertson, *Superintendent Expt'l Farm.*

Later in the season Mr. Robertson wrote under date of Dec. 15: 'The worst insect of the year with us was the Pea Aphis which was not only extremely abundant and destructive on our own farm; but judging from the number of inquiries by visitors at Nappan, about what was termed in a general way 'the blight,' it must have been very prevalent in many parts of New Brunswick and Nova Scotia.'

'Adamsville (Kent Co.), N.B., Aug. 18.—I send you herewith a stalk of pea covered with insects. All the fields of peas around here are covered with them and they kill the peas outright. I have a field infested; when I first noticed them was when the peas were in blossom. They appeared to be withered, so I examined them closely and found that they were covered with these little insects. The plants are now all withered and look as if they were rusted. I have found the insect also on vetches here. I inclose you a sample of these also; they are destroyed in the same way as the peas. I am cutting them at once for fodder. I would like to know if it will be injurious in any way to feed these vetches to cattle or horses. This enemy of the pea and vetches has never been noticed in this section before.'—A. J. Arsenault.

'Elmhurst (King's Co.), N.B.—Our field peas shortly after the formation of the pods became infested with green lice, which were to be found on all parts of the plants,

but especially thick on the pods. The plants then turned brown and dried up so as to be useless as fodder. Is there any remedy for this pest? Would it be any benefit to have the next crop at some distance from the one infested?'—C. R. PETERS.

'Thornloe (Nipissing District), Ont., Sept. 14.—My crop of peas was entirely ruined by plant-lice about half the size of a grain of wheat, which were on the plants by millions. These peas were the first ever sown on my farm, as I only came here last fall. I would like to know if this pest is often found in open country. The clearing in this part amounts to only a few acres here and there, in an immense forest of rather light young timber. If it had not been for these lice, my peas would have been a good crop, as the land suits peas, so far as they have been tried by my neigbours.'—SAMUEL REID.

'Toronto (York Co.), Ont.—I am greatly troubled this summer with green-flies, upon my sweet peas. They are in great numbers; I never saw so many as there are this year When I went along the vines with the spray from the hose, they would fall on the ground so thickly as to make it green. There was another kind which attacked the plants under the ground clinging to the roots. This is of a brick red colour but otherwise resembles very closely the green-flies which were so numerous on the leaves and stems. When I pulled up some sickly vines last summer, I also found some of these insects clinging to the roots. These latter are not so numerous as the green ones mentioned above. Wireworms, cutworms and red spiders have also given me a great deal of trouble on my sweet peas this year.'—ED. LEADLEY.

'Freeman (Halton Co.), Ont., Aug. 7.—I send a sample of peas heavily infested with plant-lice. These are from a 14-acre field belonging to my cousin, F. W. Fisher, at Burlington, close to here. This is a fair sample; I have never seen anything like it before and should like to know if it is common. I should like to know what variety of aphis this is, for it looks as if the whole crop would be lost.'—GEO. E. FISHER.

This pea aphis was also very destructive to both field peas and Sweet Peas at Ottawa, but in the case of the field peas the outbreak occurred so late in the season that most varieties ripened before much harm was done. Sweet Peas in many gardens were badly attacked. Perhaps the worst case of infestation was upon a hedge of Sweet Peas planted rather late upon the Central Experimental Farm, where an excellent opportunity was afforded of watching the development of the plant-lice and also of a war which was waged strenuously against them by various kinds of parasites. The plant-lice clustered thickly around the young shoots and towards the ends of the branches, stunting the growth of the plants very much and preventing them from flowering. They appeared at Ottawa in the middle of August, and some specimens could be found right up to the hard frosts of late autumn. By the beginning of September several kinds of predaceous insects, such as lace-winged flies, lady-bird beetles and Syrphus flies, began to appear in large numbers, and from that time on the numbers of the plant-lice decreased rapidly. When the lady-bird beetles began to pupate, they crawled up above the vines and attached themselves to the wire netting intended for the sweet peas to climb over. This they studded so thickly as to be noticeable from a considerable distance. The species which were most numerous were *Hippodamia convergens*, Guér., and *Coccinella 9-notata*, Hbst. Next to these were the larvæ of *Syrphus ribesii*, L. This latter, however, was unfortunately rather commonly attacked by the hymenopterous parasite *Bassus lætatorius*, Fab., which again in its turn occasionally fell prey to the small Chalcid *Isocratus vulgaris*, Walk. In addition to the above parasites many specimens of *Praon cerasaphis*, Fitch, were bred from material collected at Ottawa. In one garden another minute Braconid, a new species of *Aphidius*, which has been named by Mr. Ashmead, of Washington, *Aphidius fletcheri*, did good service. The empty shells—the bodies of the hosts—from which the parasites had emerged, were very abundant on the plants. These hymenopterous parasites were kindly identified by Dr. Howard, U.S. Entomologist.

I had not an opportunity to examine material from all the localities at which this plant-louse occurred in Canada during the past summer, but parasites in numbers were found at most places; and, if the Ottawa outbreak may be taken as a guide, added to the fact that although so injurious this year the Destructive Pea Aphis has never appeared in destructive numbers before, we have reason to hope that even next year it may not again be the cause of serious loss. It must be noted, however, that the occur-

rence of the parasites seems to have been extremely restricted as to locality. The *Aphidius* mentioned above was very abundant in the garden of Mr. Collingwood Schreiber at Ottawa, while hardly a specimen could be found at the Central Experimental Farm, only two miles distant, where another parasite, *Praon cerasaphis*, took its place as the abundant species. Prof. Johnson, who has made careful studies of the insect in the United States, expressly states that he has been unable to secure a single true parasite from the many hundreds of specimens he has attempted to breed. On the other hand, he found the predaceous insects feeding upon them in some localities in extraordinary numbers. Speaking of the larvæ of one of the Syrphus flies, or Hovering flies, as they are sometimes called, he mentions one instance, as reported to him by a reliable grower, that 25 bushels of the larvæ were run through his screens the last few days they were working at threshing. At the same time, hardly a Destructive Pea Aphis could be found where only a few days previously they were present in countless millions. The Syrphus flies are very active, with bodies as a rule bronzed and marked with yellow, almost like wasps. They may be recognized by their habit of remaining apparently stationary, poised in mid air for a few seconds, and then dashing off a few feet to take up another position in the same manner. The adult flies do not themselves eat the plant-lice but their elongated leech-like larvæ live entirely upon them. The eggs are laid near the colonies, and when the young grubs hatch they crawl among the plant-lice, and having transfixed one they raise it up and hold it aloft until they have sucked all the juices out of the body. They are voracious and grow rapidly, destroying a very large number of plant-lice in a day. There are several species, all of which feed upon aphides. When full grown the larvæ harden into pear-shaped puparia, and the flies emerge soon afterwards. There are several broods in a season. The lady-bird beetles are such good friends of the farmer and gardener that everybody ought to know their appearance, but there is never a year passes but some one reports having taken great pains to destroy them when they have been found in numbers, believing them to be enemies. The grubs have aptly been said to somewhat resemble small alligators. The lace-winged flies also have larvæ of somewhat the same appearance, but smaller. They are armed with long hollow jaws with which they suck out the juices of the plant-lice, and are equally voracious with the lady-bird beetles. There are many points of interest about these lace-winged flies. The eggs are beautiful objects, being attached to the end of slende upright threads. The perfect insects have gauzy lace-like wings which, when not in use, are folded together like a pent-house over the back. Their eyes are bright golden bronze.

Fig. 9.—Fifteen-spotted Lady-bird: *a*, larva; *b*, pupa.

In Mr. Leadley's letter above quoted, mention is made by him of a bright red aphis found by him on the roots of his sweet peas. Specimens of this same aphis were sent in last year by Messrs. Steele Briggs Co, of Toronto, but the species was not identified from the few specimens sent, as no winged individuals could be found. Upon the outbreak of the Destructive Pea Aphis last summer it was thought that perhaps the species concerned might be the European *Siphonophora pisi*, Kalt., but Dr. Howard informs me that this latter is a much smaller species.

Remedies.—When an insect appears suddenly in the large numbers that the Destructive Pea Aphis did during the past season and increases with such rapidity, it is evident that it would be impossible to apply any remedy over such a large acreage as was simultaneously attacked, in most places where this insect occurred; but upon green peas and the flowering sweet peas in gardens the ordinary remedies used against other plant-lice were found to be quite effective against this one also. Upon the Central Experimental Farm the Horticulturist had the plants sprayed with a tobacco-and-soap wash made of 10 lbs. of tobacco leaves in half a barrel of water, the liquid from which was strained off after a few hours, and two pounds of whale-oil soap were added. When the soap was all dissolved, water was added to make 40 gallons, and the liquid was then applied with a spraying pump. Most of the plant-lice were found to be dead two

days afterwards and on such parts of the rows as received two applications, the vines were quite cleared of the insects.

THE ASPARAGUS BEETLES

(*Crioceris asparagi*, L., and *C. 12-punctata*, L.)

Attack.—The Common Asparagus Beetle—Slender black beetles about $\frac{1}{4}$ of an inch in length, conspicuously marked with six white blotches on the back and a red border to the neck and elytra, or wing-cases, appearing in the early spring and eating into the asparagus shoots, upon which they lay their greenish black eggs. The grubs, which hatch from these eggs, are dark olive and slug-like. These also attack the shoots. The Twelve-spotted Asparagus Beetle :—Occurring sometimes with the above, are beetles of about the same size, but slightly broader and of a uniform reddish orange colour, with twelve black spots upon the wing-cases. The grubs somewhat similar to those of the Common Asparagus Beetle, but of a dirty yellowish colour, feed inside the berries of asparagus.

Fig. 10.—The Common Asparagus Beetle : different stages on asparagus spray.

Both kinds of Asparagus Beetles have been common in some parts of the Eastern United States for many years. The former obtained a permanent foothold on this continent in 1856, and the latter in 1881.

THE COMMON ASPARAGUS BEETLE.—The first record of this insect, as a crop pest, in America was at Astoria, near New York city, in 1862. In a most complete article on the subject, by Mr. F. H. Chittenden in the United States *Year Book* for 1896, it is stated as follows :—"From the seat of its introduction at Astoria, forty years ago, it soon spread to the asparagus farms of Queen's County, N.Y., and by 1862 it was reported to have occasioned the loss of over a third of the crops of certain localities, such loss being estimated at $50,000."

The Common Asparagus Beetle is now found as an enemy of the asparagus plant in most of the North-eastern States, lying in the Upper Austral faunal zone. Its distribution is by means of the adult beetles flying, and by their transportation to new localities with the roots of asparagus.

Last year it was reported by Mr. A. H. Kilman (*Rep. Ent. Soc. Ont.*, 1898) that it had reached the Niagara River in the State of New York, and during the past summer it occurred in injurious numbers in the Niagara peninsula of Ontario. The first Canadian specimens sent to me were from Mr. E. Arnold, of Queenston (Lincoln Co.), Ont., and upon enquiry I learn that many asparagus beds in the Niagara district were much injured last season. Mr. John Dearness, a member of the San José Scale Commission, informed me that during 1899 he had seen the beetles abundant and injurious near St. Catharines, Ont., where also he had found that the beds were badly affected with the Asparagus Rust (*Puccinia asparagi*, DC.)

a

Fig. 11.—The Common Asparagus Beetle —enlarged.

The Common Asparagus Beetle is a narrow black beetle a little less than $\frac{1}{4}$ of an inch in length and very prettily marked. The head legs and feelers are blue black, the thorax is chesnut red, the wing-cases are mainly blue black with six silvery white spots and are widely bordered around their edges with orange red. The markings on the wing-cases have, as shown in the illustration, somewhat the appearance of a double black cross. The wing-cases are shining and bear several longitudinal lines of deep punctures. This insect injures asparagus both in the larval and perfect states. The perfect beetles pass the winter hidden beneath rubbish, loose bark of trees or stones, and appear just at the same time as the asparagus comes up, when they fly to the buds and begin to eat into the succulent shoots, upon which also they lay their eggs. These are brownish black in colour, large, compared with the size of the beetle, being nearly one-sixteenth of an inch in length, nearly three times as high as wide, and stand out in every direction from the shoots. They are attached by one end and are laid on the shoots, and later on the foliage, in rows of 6 or 7 eggs. The young grubs hatch in a few days and are grayish with black shiny heads and legs, admirably shown in figure 12 *c*. They at once attack the young shoots, eating into them, and when touched these larvæ also emit a dirty blackish fluid which soils the shoots, spoiling them for the market. They are very voracious and grow rapidly, becoming full grown in about a fortnight, when they are dark greenish-gray, shiny bag-like grubs (Fig. 12*d*), which crawl quickly but clumsily, drawing up their bodies and attaching themselves by their anal prolegs to the object upon which they are crawling. When ready to pupate, the grubs burrow into the ground and change to yellowish pupæ (Fig. 12*e*). In about a month from the time the eggs are laid, according to Fitch, the perfect beetles appear. There are probably two broods in a season in Canada. Mr. Chittenden says (*loc. cit.*): "The minimum life-cycle period of the species in the District of Columbia and southward is about three weeks from the time the egg is laid. In the colder climate of New England and in spring and summer weather the development from the egg to beetle will require from four to perhaps seven weeks. In its northern range two and perhaps three broods are usually produced, and further south there is a possibility of four or five generations each year."

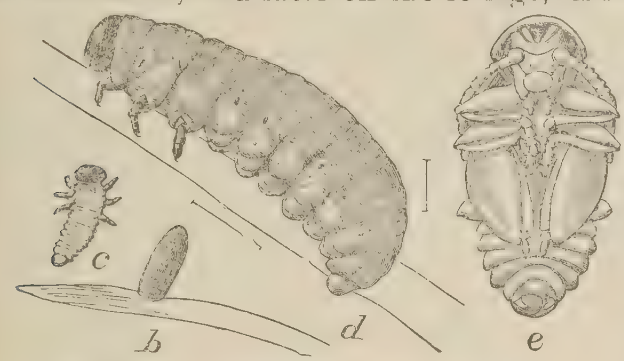

Fig. 12.—The Common Asparagus Beetle: *b*, egg; *c*, *d*, larvæ; *e*, pupa—enlarged.

Fig. 13.—Egg of Spotted Asparagus Beetle—enlarged.

THE TWELVE-SPOTTED ASPARAGUS BEETLE is about the same length as the above but is a slightly broader insect. The general colour is orange red, and the wing-cases bear 12 round black spots, the knees are also marked with black. This species was a much later introduction into America than the Common Asparagus Beetle, not having been noticed until 1881, when it was found in considerable numbers at Baltimore, Md., by Prof. Otto Lugger. It has, however, spread rapidly and now occurs with, and covers almost the same area as, the Common Asparagus Beetle.

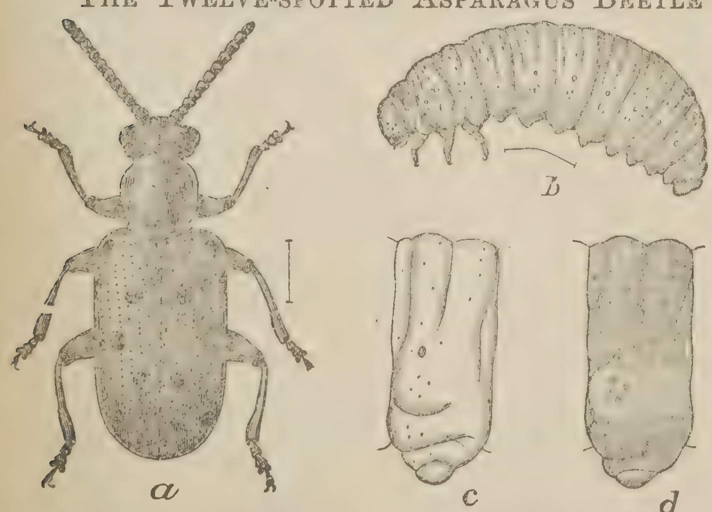

Fig. 14.—The Twelve-spotted Asparagus Beetle: *a*, beetle; *b*, larva; *c*, 2nd abdominal segment of larva; *d*, do. of *C. asparagi*—*a*, *b*, enlarged; *c*, *d*, more enlarged.

In the Canadian occurrence of these beetles during the past summer, both

species were about equally numerous on the infested beds. In the United States the 12-spotted Asparagus Beetle is regarded as rarer and less injurious than the common species. Although the hibernated beetles appear equally early in the season with the Common Asparagus Beetle and attack the young shoots, Mr. Chittenden states (*Bull. 10*, n.s., U.S, Div. Ent.) that the larvæ live chiefly in the green and ripe fruit of the Asparagus. There are, however, several records of serious injury by this species in early spring to the growing crop. Mr. Chittenden has described the eggs and the method of oviposition as different from those of the Common Asparagus Beetle (*Bull. 10*). Instead of being attached by one end and having the surface sculptured, these are attached to the plant by their sides as shown natural size and enlarged (Fig. 14). The larva also differs much (Fig. 14 *b*, *c*). Mr. Chittenden thinks that these larvæ live almost entirely in the berries, each one passing from one that it has excavated to a fresh one when in need of food. The berry drops off soon after the larva enters it, and the first brood of the beetles matures long before the berries redden on the plants. The same writer also gives the following very accurate description of some of the habits :—It is about the same size and proportions as the larva of the common species but is readily separable by its ochraceous orange colour. The ground colour is light yellowish cream overlaid with ochraceous orange ; the head, with the exception of the mouth parts, is also ochraceous. Thoracic plate dark brown divided into two parts.

Mr. Chittenden gives the following very accurate description of some of the habits of these insects :—"The Twelve-spotted Asparagus beetle, as it occurs on the plant when in fruit, very closely resembles at a little distance the ripening asparagus berries. The Common Asparagus Beetle, as is well known, dodges around a stem like a squirrel when disturbed, but the Twelve-spotted form appears to trust to flight, taking wing more readily than the other. Both species make a loud creaking sound when handled. This stridulation is produced by rubbing the tip of the abdomen against the elytra."

Figures 10 to 14 in this article have been kindly lent by Dr. L. O. Howard the U. S. Entomologist.

Remedies.—Owing to the inadvisability of applying any poisonous substances to the young shoots in spring, at the time they are being cut for the market, with the object of destroying the hibernated beetles, remedies should be directed mainly against the larvæ which appear on the plants during the summer. There are many useful measures which may be taken to control these insects :—

1. Dusting with lime.—Perhaps the most effective is the destruction of the larvæ by dusting the plants at short intervals, every three or four days, with fresh air-slaked lime, which adheres to their slimy bodies and quickly kills all those with which it comes into contact. This is best done early in the morning when dew is on the plants.

2. Arsenites.—Active poisons, as a mixture of Paris green and flour, or Paris green and lime, applied dry to the grown stems in the same way as for the Colorado Potato Beetle, answer well, and kill not only by contact with the larvæ but destroy both the larvæ and the perfect beetles when they eat the poisoned foliage.

3. Beating.—The beetles and many larvæ may be beaten from the asparagus plants into nets or broad pans containing water and coal oil. Nets made specially for the purpose are most convenient. A good pattern for an easily made net which can be held beneath the plants with one hand while the insects are beaten down on to it with a light rod, has a stick on each side and a flat sheet of cotton between, three feet wide at the top and one foot at the bottom (Fig. 15). Two cross bars close together at the base allow of this net being easily held by taking the upper bar in the left hand, so that the lower bar rests against the back of the wrist. The larvæ may also be brushed off the plant with a stick, and, if this is done in the middle of a hot day, it is claimed that few of them get back again, a very short time in the hot sun proving fatal.

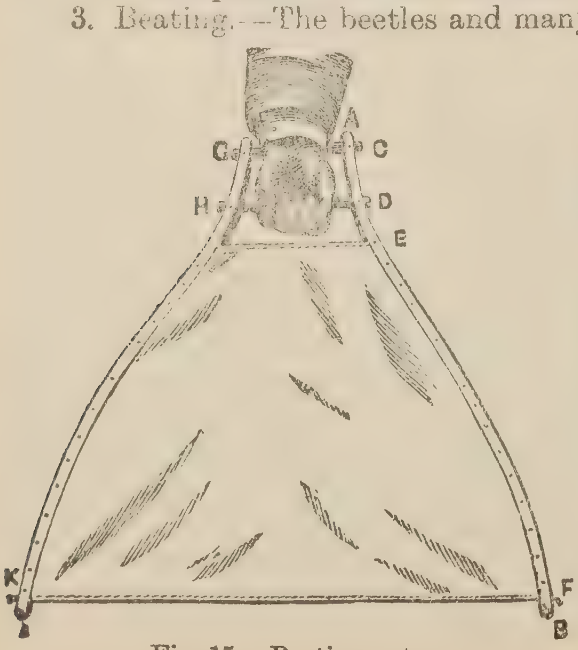

Fig. 15.—Beating net.

4. Traps.—During the cutting season the crop should be kept well down, a few shoots being left to attract the egg-laying females. In a week or so these should be cut and destroyed, other shoots being left to take their place. Young beds not old enough to be cut should be kept dusted with lime.

5. Poultry.—Chickens and ducks when available are very useful in eating the beetles when they first appear in spring, and it is claimed they do no harm to the beds.

THE BLACK VIOLET APHIS

(*Rhopalosiphum violæ*, Pergande).

Attack.—Dark coloured plant-lice clustering beneath and about the bases of the leaves and penetrating into the heart of violet plants grown under glass for winter flowering, sucking the plants and injuring them so as to prevent them from flowering, the growth being stunted and the leaves curled up.

During the convention of the Canadian Horticultural Society held at Ottawa last September, Mr. J. H. Dunlop, a large florist of Toronto and an extensive grower of violets under glass, asked what could be done to prevent the attacks upon his violet plants by the Black Violet Aphis, which he stated had been a cause of considerable loss in his greenhouses. On October 13, a visit was made to Mr. Dunlop's establishment by Mr. Arthur Gibson, of this Division, and specimens of the plant-louse mentioned were secured. These have since been bred in confinement, and specimens have been kindly identified by Mr. T. Pergande, through Dr. Howard's courtesy, as *Rhopalosiphum violæ*, a species lately described by Mr. Pergande. As a plant-louse, when examined closely, this is a very beautiful species, the body being of a brownish green, marked with black patches, and the stigma and all the veins of the wings are clearly and broadly marked with black. At the time of Mr. Gibson's visit, the aphides were very numerous, almost every plant examined in most of the violet houses being found to be infested. Very little systematic work had been done at that time towards controlling these insects. Mr. Dunlop was of the opinion that, as is known to be the case, the violet is easily injured by tobacco fumigation; consequently, little smoking had been done. Later, however, the attack became more serious and was the cause of a loss in this year's violet crop, estimated at $1,000. Fumigation with tobacco had been resorted to for three weeks at intervals of one week apart, at the time of a second visit paid by Mr. Gibson on December 26. Powdered tobacco stems had also been dusted over some of the plants. These applications had killed many of the aphides, and the insects were then practically under control, but the plants were showing many spotted leaves. The treatment of violet plants with tobacco is considered objectionable by the best growers. Mr. B. T. Galloway, Chief of the United States Division of Vegetable Physiology, who has studied the commercial culture of violets and is the author of an excellent book upon that subject, writes as follows with regard to some leaves which were submitted to him from Mr. Dunlop's houses where the fumigation had been done:—'The violet leaves are affected with the well-known spot which is very apt to appear at almost any season of the year under certain conditions. In our experience we have never found it safe to use tobacco in any form on violets; even the very weakest fumigations have a tendency to weaken the foliage and bring on spot. My suggestion in this case would be to thoroughly clean the plants, withhold water from the foliage for two or three weeks and keep a night temperature of about 40 degrees, with a day temperature of 55 or 60 degrees. In other words, attempt to give as good conditions as possible to bring the plants to health.'

Remedies.—For greenhouse plant-lice and certain other insects, the most generally adopted method to prevent such attacks is the fumigation with tobacco in its various forms. In the case of violets, however, as Mr. Galloway states, the tobacco fumigation tends to weaken the foliage and cause the 'spot' to appear. In an excellent bulletin recently issued by the United States Division of Entomology (*Circular No. 37, 2nd*

Series), the use of hydrocyanic acid gas for greenhouse fumigation is recommended, as of particular value to violet growers. Indeed this line of application of the gas is said to have been specially devised for violet houses by Messrs. Woods and Dorsett, the authors of the bulletin, who are officers of the Division of Vegetable Physiology and Pathology, and the latter is a practical violet grower. Careful and exact directions as to the proper way of using the gas, together with the necessary precautions which must be taken to avoid danger to the plants or to the operator, are given. Different plants are liable to injury in a varying degree, so that it becomes necessary to know the strength of the gas which may be used with each class of plants. Many experiments have been tried with this end in view, and directions are given in the bulletin cited for some of the leading greenhouse plants, e.g. :

'Double English Violets.—"Marie Louise," "Lady Campbell," and others. For plant-lice and general fumigation, fifteen-hundredths of a gram of 98 per cent cyanide of potassium for each cubic foot of space is required. The exposure, if made according to directions, will not hurt the plants in any stage of growth. The gas has been used on a large scale in fumigating violets for the past three years with the greatest success, only a few treatments during the season being required. Leaf-eating larvæ, slugs, millipedes, cutworms, &c., when exposed, are killed as well as plant-lice. Red Spiders, however, are not entirely eradicated by the treatment. The foliage of single violets like California and Princess of Wales are sometimes slightly injured by the stronger dose of gas. A weaker dose (one-tenth of a gram cyanide of potassium per cubic foot) should be used when they are to be treated.'

THE CLOVER MITE

(*Bryobia pratensis*, Garman).

Attack.—Reddish brown mites $\frac{1}{25}$ of an inch in length, oval in shape and with remarkably long front legs, causing the leaves of fruit and other trees, as well as of clover, to turn yellow.

This species of mite belongs to the same family of vegetable feeding mites, the *Tetranychidæ*, as the ordinary so-called 'Red Spider,' often found on house plants and in conservatories, and which also attacks orchard trees, rose and currant bushes, sweet peas, and other low plants, causing the leaves to assume a sickly appearance and to dry up. The eggs of the Clover Mite frequently come in from inquiring correspondents. They are ruby red in colour, broadly rounded above and comparatively large, about $\frac{1}{100}$th of an inch in diameter. They are usually deposited in large flat mat-like clusters in and around crotches of the branches of orchard trees, particularly of plum trees, and often in sufficient numbers to give a distinct red colour to the bark. Specimens of eggs were received first from British Columbia, and since then have come from many parts of Ontario, and as far east as Gaspé in the extreme east of the Province of Quebec.

Though spread over such a large territority in Canada, the Clover Mite does not seem to have attracted attention by its injuries anywhere except in British Columbia, until last summer, when the following letter was received :

'Queenston (Lincoln Co.), Ont., July 17.—With this I send you some twigs of some Niagara Plum trees. They are much paler green than others and are evidently affected by some insect, possibly the Red Spider. Did you ever know this insect to work on plum trees in this manner? The entire foliage of large trees seems affected. What had I better do to check it? Is it dangerous?'—C. E. FISHER.

In Canada the Clover Mite passes the winter in the egg state, but in many parts of the United States it has been complained of from time to time in the last ten years as an unwelcome invader of dwelling houses in the mature state, during autumn and winter. The small size of the Clover Mite enables it to go through ordinary wire screens with ease to the serious disquietude of the house-keeper.

The large number of inquiries about this mite, both on account of its invasion of houses in autumn and of its injuries on trees and other plants, made it necessary for the United States Entomologist to publish a special circular on the subject (*Circular No. 19*, Second Series).

Though the injuries to fruit crops by the Clover Mite have not been serious in Canada east of the Rocky Mountains, a good deal of harm is done in the Pacific States and in British Columbia to many fruit trees, particularly plums, apples, almonds and cherries, and together with other kinds of mites this is often spoken of under the general name of 'Red Spider.' Besides the injuries above referred to, there is no doubt much damage is done by this insect to clovers and grasses which is overlooked.

Remedies.—The protection of fruit trees from the attacks of this mite is not difficult where the winter is chiefly passed in the egg state on the trunks of trees. It has been found that spraying the egg masses during the winter with kerosene emulsion diluted with five parts of water will destroy the eggs without injuring the plants. Their entrance into houses in autumn may be prevented by spraying the lower portions of the buildings with pure kerosene, and, if the mites are found infesting grasses or other plants, these latter should also be sprayed with kerosene emulsion diluted with nine parts of water, to which some finely powdered sulphur can be added with advantage. When the mites have gained access to a house, they may be destroyed by the free use of pyrethrum insect powder or by burning brimstone in the room. Gasoline or benzine may be sprayed over them, but these liquids are dangerous from their extreme inflammability, and hot water frequently applied would answer the same purpose.

THE GREENHOUSE LEAF-TYER

(*Phlyctænia ferrugalis*, Hbn.).

Attack.—Slender semi-translucent green caterpillars, when full grown nearly an inch in length, with two distinct black spots close behind the head, the green dorsal vessel showing distinctly down the middle of the back, bordered on each side with a double white band, feeding inside a slight tent made by drawing the sides of leaflets together with silk threads. The cellular tissue of the lower sides only of the leaves is eaten.

During the past summer I had brought to my notice injuries to roses in the greenhouses of Mr. J. H. Dunlop, of Toronto, by the caterpillars of a small European moth, which has been introduced into America for some years and has been occasionally noticed as a greenhouse pest, and on one occasion as injuring celery out of doors in Michigan. Mr. Dunlop first noticed the work of this insect about three years ago, when it destroyed the whole of the roses in one of his houses, and did much harm in others. The only effort to control it was by catching the moths and destroying them. Every year since 1897 the caterpillars have been the cause of some loss. On October 13 last, Mr. Arthur Gibson visited the houses and saw large numbers of the moths flying among the roses and resting on the sides of the house. Living caterpillars were also found of all sizes at this time and appeared to feed almost entirely on the under sides of the leaves, eating away the soft green tissues and spoiling the appearance of the foliage. From the time they hatch until full-grown, the caterpillars live in tents made by drawing down the leaflets of the leaves; the cocoons are spun between the leaves. In a work entitled *Commercial Violet Culture* by Mr. B. T. Galloway, of Washington, it is stated that violets are sometimes attacked during the summer by this insect, the larvæ attacking the leaves and destroying the softer parts, leaving only the skeleton or frame of the tissues. The caterpillars are surrounded by a light web and occasionally two leaves are fastened together to give them protection. It is further stated that the insect never produces serious injury, but it is advisable to watch for it and take such steps for it as may be practicable. The picking of the leaves containng the larvæ is recommended and, if it should become abundant, fumigation with hydrocyanic acid gas.

A second visit was made on December 26, and although the specimens were many fewer, the houses having been carefully gone over, a moth was found flying, and a cocoon containing the living pupa, but no caterpillars. Mr. Dunlop states that the caterpillars may be found all through the winter.

The following description was taken of the larvæ :

Full-grown caterpillar,—Length at rest, $\frac{3}{4}$ of an inch. General appearance : slender, semi-translucent green caterpillars with the dark green dorsal band showing distinctly through the skin, rather fainter on 2nd, 3rd, and 13th segments. This is bordered on each side by a double white sub-dorsal band, which also is rather fainter on the 2nd, 3rd and 13th segments. On the 2nd segment are two distinct black spots, one on each side. Head one-twenty-fifth of an inch in width, smooth and shining, whitish, splashed with light brown on the cheeks, slightly furrowed at vertex, and bearing a few pale hairs. Mandibles brownish ; ocelli black. Spiracles white and very small, joined by a faint whitish line. On the 2nd, 3rd and 4th segments this line is represented by a few faint white dots and is obsolete on segment 13. Thoracic feet and prolegs of the same colour as the body ; the thoracic feet each bear exteriorily two black dots, one above the other. The whole body is sparsely covered with slender pale hairs, the ventral surface lighter in colour than the dorsal. When at rest these caterpillars have a habit of curling round to the side of the body, their heads and the first three or four segments of the body. The length of the pupal period in October was 17 days.

THE RASPBERRY WEB-WORM

(Lyda multisignata, Nort.*)*.

Attack.—Bright green smooth false-caterpillars, when full-grown over half an inch in length, which web together many of the leaves on raspberry canes, making a tent in which several of the caterpillars feed together.

A rather interesting new enemy of the raspberry has for some years occurred at St. John, N.B.; larvæ were received in 1898, from which two males and a large number of female saw-flies were reared last summer. These have been kindly identified by Dr. Howard as *Lyda multisignata*, Nort. The caterpillars when full-grown are over half an inch in length, the head round and smooth, the cheeks and back of the head chestnut brown, as well as the mandibles, and a large round patch in front of the face. Ocelli black. On the segment next to the head is the thoracic shield, which in some specimens is also darkened with brown patches, and on each side of the throat beneath, running across the same segment, from the back of the head to the bases of the first pair of thoracic feet, is a short dark brown chitinous band. Antennæ 7-jointed, and for caterpillars conspicuous. On each side beneath the last segment is also a 3-jointed antenna-like appendage protruding downwards. These appendages in *Lyda* are called abdominal antennæ by Dr. A. S. Packard in his *Text Book of Entomology*, 1898, page 165, and a figure is given of a *Lyda* larva which might almost be used as an illustration for the species under discussion. The upper flap of the last segment is rounded at the tip and bears three dark triangular marks extending from the base towards the apex, but not reaching it ; the median, only half the length of the lateral ones ; lying in a depression at the extremity, there is also a distinct median dark dot. The lower flap of the last segment, dark brown narrowly margined with green, and as well as the upper, bearing a sparse fringe of short slender bristles.

This attack was first brought to my notice by Mr. George Raymond, of Bloomsfield (King's Co.), N.B., who wrote under date August 1, 1898 :—'A friend of mine in St. John has a small garden, where she has been growing raspberries for a number of years. For the last six years they have been troubled with a worm on the leaves, at first very small, and on the under side. As they grow, they spin a web drawing the leaves all round them and destroying the foliage. They have been much more destructive this year and it is only by persistent picking of the leaves that they can be kept in check.'

Miss H. Raymond, in whose garden the injury was done, wrote a full account covering most of the facts mentioned above, but stating that the larvæ were gregarious, about six being found in the same tent, and from her account and from specimens forwarded to the Division the attack of this species upon raspberries resembles very

closely that of another Lyda which has been found in southern Manitoba upon plum trees (*Lyda rufipes*, Marl.) and was treated of in my report for 1896 at page 253.

Upon rearing the perfect insects, which emerged at Ottawa from the middle to the end of June, specimens were sent to Miss Raymond, and she subsequently wrote saying that she had often seen these flies upon the raspberry bushes about the middle of June. She also stated it was about six years since the insect had appeared in troublesome numbers, and it had been worse during the past four.

Remedies.—As these caterpillars appear on the raspberry bushes at the time the berries are forming, it is inadvisable to use Paris green and similar poisons. Moreover, Paris green has been found to be more injurious to raspberry foliage than to some other plants; if therefore poisons are used, the vegetable poison, white hellebore, is preferable, because, although very fatal to many insects and particularly to all kinds of sawfly larvæ, the poisonous principles, being very soluble, are soon washed away by rain and dew, and there is little danger in using the fruit a week after an application of white hellebore. As, however, the tent-like webs are very conspicuous and this is certainly a very uncommon insect, the method of handpicking which has been successfully adopted by Miss Raymond, will probably in most outbreaks answer all purposes.

THE APIARY.

The following report has been handed in by Mr. John Fixter upon the Apiary, at the Central Experimental Farm, the management of which as heretofore has been left entirely in his hands.

REPORT OF MR. JOHN FIXTER.

THE SEASON OF 1899.

April 1.—Eighteen colonies were removed from the winter quarters: six were placed in the House Apiary, six in the sheltered apiary, and the other six in the exposed apiary. In the case of the two last there was a considerable depth of snow on the ground, from 1 foot to 18 inches, The hives had to be watched as the snow melted to prevent them from toppling over. From April 1 to 4, there was scarcely any flying, but from the 15th to the 17th, there was much more. The hives in the exposed apiary were covered with coarse sacks as a protection, leaving a very small entrance for the bees. In the sheltered apiary and House Apiary no such protection was given. The bees in these apiaries appeared to work better than those which were exposed. On many days when the weather was cool, with cold winds, those that were sheltered were flying well, while none of the others were.

The balance of the colonies were taken from their winter quarters on April 17. All began to fly at once and no mixing appeared to take place. The colonies that were set out early were flying as well as is usual in the month of May. From April 17 to 23, many of the bees were flying every day, when the first pollen was noticed, being brought in off the swamp maples and willows. From April 20 to 30, the bees were seen gathering sap off hard maples that were running, and also off hard maple stumps where trees had been lately cut.

From May 1 to 15 the bees gathered a great amount of pollen, but very little new honey, and nearly every hive was full of brood and young bees—the first drones were noticed May 24. A considerable amount of honey was fed from May 15 to June 1, so as to keep up brood rearing and to prevent starving.

Up to June 1 there were many flowering trees and shrubs in bloom, but there was no increase in honey. From June 1 to 6, the bees were flying well, gathering pollen, but no increase in honey. On June 6 Alsike Clover came into bloom. Up to June 17 there was no honey gathered. From June 18 to 30, the bees gathered a great deal of honey from clover and raspberry.

On July 3 the first honey was taken off. July 8 the basswood trees were well out in bloom, bees appeared to be very thick on the flowers, but there was very slight increase in weight of hives; during the balance of July, bees gathered very little honey, and there was no increase in the weight of the hives after August 1. The autumn flowers gave no surplus, and there being no buckwheat sown in this district in 1899, no honey was gathered from that source.

The season being such a poor one for honey gathering, all the summer experiments have been left for another season. It is intended to test the different hives with equally strong colonies—Langstroth 8 and 10 frames, Jones hive and Hedden hive—also to test each kind for comb-honey and extracted honey; different-sized sections and further different-sized pieces of foundation in the sections.

House Apiary.

The House Apiary was again tested with two tiers of hives. This plan can be safely recommended for cities or towns where space is limited, and two tiers can be arranged just as well as one in the same building. This plan can also be highly recommended in sections of the country where the hives are continually being disturbed by boys or in any unused buildings which can be locked up.

Returns.

The past season has been a very poor one, both as to the quality and as to the quantity of honey. The returns per hive of the Central Experimental Farm Apiary for the season of 1899 show an average of only eighteen sections per colony. The colonies which were run for extracting gave 23 pounds per colony. Swarming was well kept under, very few colonies being allowed to swarm. The total number of colonies at the end of the season is sixty.

NOTES ON SUMMER MANAGEMENT OF BEES.

There is scarcely a place in Eastern Canada where bees cannot be kept profitably. There are, of course, some localities more favourable than others for the purpose, and there are certain seasons which are so unpropitious that bees have to be fed and little or no surplus honey is stored; but, on the whole, with careful management, bee-keeping may be made not only a remunerative occupation but a source of a great deal of pleasure to those engaged in it.

The keeping of bees may be practised almost anywhere, even in large cities, in towns or villages, as well as on the farm. In cities or towns the hives may be placed on the roof of any building where they get some shade, or, what is better, the hives may be kept inside a room, as explained under the head of House Apiary in previous reports. An important point, however, is to place them where they can be watched carefully during the swarming season.

I would advise placing the hives on their summer stands early in spring without waiting, as is done in many sections, until the soft maples and early willows bloom; but advantage should be taken of the first calm day when the temperature is about 60 degrees. When carrying the bees out, have weighing scales near at hand, also clean bottom boards to replace those which have been in use all the winter, and which must be cleaned before using again. Weigh at once and note the number and weight of each hive, the number for reference, and the weight to know what amount of stores is still left to carry the colony over until the honey flow. On a very warm day when there is no

wind, examine each colony and see that it has a good laying queen and plenty of stores. Should there be insufficient honey, give them a frame of honey with the cappings scraped off, placing it as close to the brood as possible, also close the entrance more or less according to the strength of the colony. If the colony is very strong, the entrance may be left about two inches in width; if weak, close down to about one-half inch. Great care should be taken to protect the hives from cold draughts in spring. As the weather gets warmer and the colonies stronger, open the entrances. On many days the bees in the House Apiary and in the sheltered apiary will be flying and gathering pollen, while the bees in the exposed apiary are at home keeping the cold air off the brood. If you have a propolis quilt or chaff cushion on the hives, leave it there until the colony is strong enough for a super for sections, or for extracting frames; then all should be removed.

The time for putting on supers is when the hive is full of bees and there are good prospects of a honey flow; by allowing plenty of room, swarming will be prevented to some extent. In this section of the country great care should be taken to see that each colony has plenty of honey during the period between the fruit bloom and clover bloom. A any failures at this time are due to lack of stores, and too much attention cannot be paid to this point. I would advise feeding if necessary up to the clover bloom to force brood-rearing, so as to have the colonies strong. Excessive swarming may be forced or prevented as desired.

If swarms are desired, crowd the bees and stimulate them with syrup. I would not advise allowing more than one swarm from each colony. To prevent excessive swarming give the bees plenty of room and do not wait until they swarm, but put on the supers as soon as the colony is strong enough to work in them. Should swarming occur, remove the hive to another stand, take a new hive, put the swarm into it and place it on the stand from which the swarming hive was removed. The old colony may be further weakened by taking out several frames and shaking all the bees off in front of the newly hived swarm.

For hives placed in a garden choose some convenient place near the dwelling where those busy about the house can see any swarms as soon as they leave the hive and settle. It is better to locate the hives away from the immediate proximity of high trees because when the bees swarm they are apt to settle too high up to be secured without much trouble. When gathering a swarm, a most important help is Manum's wire cloth swarming device, or a similar one, even a large pail attached to the end of a pole, will answer. The use of these will save many swarms and many stings for the operator. The pole may be made in joints so as to allow of extension to the required height There are many patterns of swarm collectors, most of which consist of a ring of stout wire about 2 feet in diameter, bearing a bag of some light material of about 2 feet in length. This is put up beneath the swarm and the bees shaken into it. It is then lowered and the bees are emptied out in front of a new hive, already prepared for them.

Swarms which settle on shrubs, are much more easily handled. All that is required is to take a piece of sacking, spread it on the ground under the swarm, place the hive properly prepared on the sacking, give the limb or shrub a sharp jar, when the swarm will drop in front of the hive and at once enter it. Another excellent plan is to take a frame of drawn comb or a frame of unsealed brood, and draw it up against the swarm; a large majority of the bees will soon gather upon the frame, which should then be placed in a hive with several more frames. Those bees which have already clustered on the frames will begin to call their companions; as soon as a few have found the entrance they will announce their discovery by the usual vibration of the wings ('humming'). Should the swarm still cling to the tree or shrub, a bunch of grass or a twig from an evergreen is useful to brush them off with. The hive should be left until the bees have all entered it, and as soon as they have done so, the hive should be carried to its permanent location in the apiary. If the colony is a strong one and the season favourable, place at once on the hive a super or extracting frames. When the honey flow and swarming seasons begin, everything should be in readiness to receive the swarms. Supers should be filled with sections, each of which is provided with a full sheet of foundation, and the extracting frames should also have full sheets of foundation in them, and must be

wired so as to prevent the heavy combs from breaking when the honey is being extracted. Even in the brood frames, full sheets of foundation are preferable, except perhaps for some expert apiarists.

The time to remove section honey is when the supers are fairly well filled and capped; it is best not to wait until the corner sections are filled, as these if not full enough may be put back into the next super. When removing the section honey, start shortly before sundown, smoke the bees at the entrance, then take a wide chisel and gently pry off the super and stand it on end, close to the entrance of the hive; leave it there a short time, then remove it to the honey room, leaving the doors and windows open all night for such bees as still remain on the comb to escape. By the following morning all the bees will have either returned to the hive or gone to the fields. The doors and windows of the honey room should be closed very early the next morning, or robbing will take place. Comb honey should not remain on the hive to be daubed after the sections are sealed. Remove the honey to a very warm dry room, where it will ripen thoroughly. The extracting frames may be left on the hive to ripen until the busy honey season is over; they may be tiered up two or three high. When an empty super is added, put it at the bottom next to the brood chamber. When removing extracting frames, a bee-escape is placed between the extracting super and the brood chamber, and at night the bees will descend through this but cannot return again, When all the bees are down, remove the frames to the extracting room. All honey, whether in comb or extracted, should be kept in a warm, dry room.

JOHN FIXTER.

THE WORST WEEDS OF THE NORTH-WEST.

Strange as in may seem, it is no easy matter to decide off hand what is the *worst weed* in a district, and even in a single locality there is frequently great diversity of opinion on this point. Judging from the replies of correspondents, the 'worst weed in the district' seems to mean the one plant which has given most trouble at a recent date to the farmer who happens to be interrogated.

There are, however, certain plants which, for one reason or another, every year prove to be troublesome and aggressive enemies of the farmer, causing loss of crop, necessitating extra labour, or compelling him to treat or utilize his land in a way other than he would wish.

From a close study of this subject in the West during the past five years and after consultation with the energetic and competent Weed Inspectors of Manitoba and the North-west Territories, Messrs. Charles Braithwaite, of Portage la Prairie, Man., and T. N. Willing, of Regina, N.W.T., respectively, it seems to me that the following plants are specially noxious, and every effort should be put forth to destroy them when detected, or to prevent their introduction to new localities.

STINK WEED or Penny Cress (*Thlaspi arvense*, L.), miscalled sometimes 'French Weed.' Annual. Introduced. A most pernicious and persistent weed with a strong nauseous odour and which endures the lowest temperatures of the West with impunity. Young plants overtaken by winter before their seeds are formed, revive in spring and mature in June; the seeds are produced in enormous numbers, and there are two complete crops ripened every year. This plant belongs to the same natural order as the mustard and cress, the turnip, and the cabbage. The milk of cows which eat it, is tainted and unfit for food. As a field pest it is a vigorous grower, crowding the crop and robbing the land of moisture. The succulent nature of the leaves and stems render it very dificult to kill unless destroyed when quite young.

Remedy.—Plough down before the seed pods form and harrow fallow-land constantly so as to destroy all seedlings. Land for summer-fallowing upon which plants with fully formed pods occur, must be mowed over and the plants burnt before turning down.

Land under grain crops should be harrowed two or three times with a light harrow having sloping teeth or with a weeder, from the time the grain is two inches high until it is six or even eight inches. Mr. Willing says 'Stink Weed is decidedly the hardest weed we have to handle, and some of it has been found in all districts where farming has been carried on to any extent from Manitoba to the foot hills, and from the United States boundary to the Saskatchewan.'

Wild Oat (*Avena strigosa*, Schreb.).—Annual. Introduced. Closely resembles some varieties of cultivated oats, but ripens its useless hairy seeds irregularly, so that many fall to the ground before the grain they grow among is ripe, thus crowding the crop and infesting the land with a useless and aggressive weed. Mr. Braithwaite says: 'After Stink Weed, the Wild Oat has certainly done farmers the most harm this year.' There are in Canada three kinds of Wild Oats which have been introduced from Europe. The kind most abundant in many parts of the North-west and British Columbia is the Black Wild Oat (*A. strigosa*).

Remedy.—The best means of clearing land of this pest is to work it in early spring and, when many of the seeds have germinated, go over it again with a disc harrow and sow a very early variety of oats or barley, to be cut twice as green feed and then turned down. If this land can be used the following year for a hoed crop or roots it will be better than sowing grain.

Canada Thistle (*Cnicus arvensis*, Hoffm.).—Perennial. Introduced. The Canada Thistle, so-called, is extremely abundant in some of the rich lands of the Red River valley and is well established in many spots right across the continent to the Pacific. West of Manitoba, however, it is far less troublesome than many other weeds. Mr. Braithwaite says: 'I may say I am more concerned about Canada Thistle and Tumbling Mustard than any others of our weeds. The Thistle is spreading rapidly from vacant government lands north and east, and the Tumbling Mustard has spread from the North-west down through the Souris districts.' Mr. Willing views its spread in the North-west with anxiety; he says, 'Canada Thistle seems to have come to stay and is very plentiful along the northern branches of the railway, but, it is true, many other weeds as yet are giving more trouble to farmers.

Tumbling Mustard (*Sisymbrium altissimum*, L.).—Annual. Introduced. This coarse member of the Mustard Family was only introduced into the wheat fields of the West about ten years ago, but it has now spread from Indian Head, where it was first noticed, eastward through Manitoba and westward to the interior of British Columbia. Mr. Willing says 'Tumbling Mustard is now more plentiful than any other weed in south-eastern Assiniboia.' Tumbling Mustard has all the bad charac-

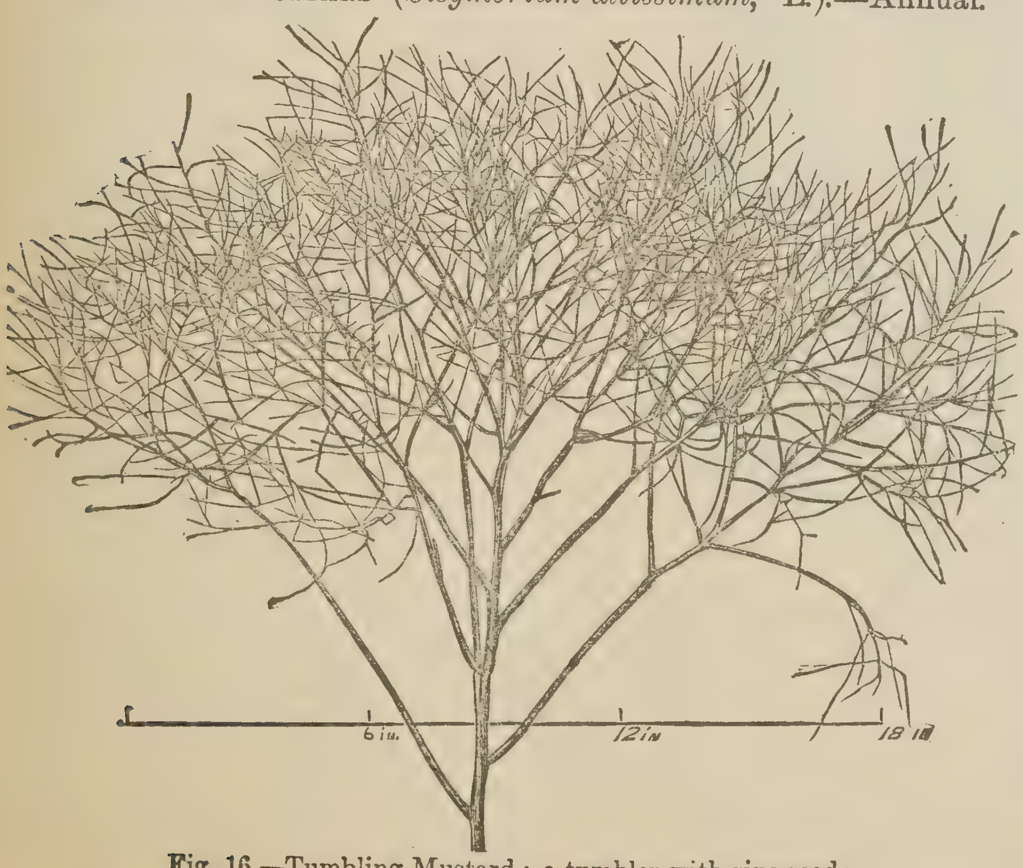

Fig. 16.—Tumbling Mustard: a tumbler with ripe seeds.

teristics of the other mustards and besides is a large free-growing, exceptionally prolific plant, of which when the seeds are ripe the head breaks off and becomes a 'tumbling weed' (Fig. 16), which may be blown for miles across the prairies in the autumn and during the winter, thus scattering the seeds quickly over wide areas. The reddish or greenish-brown seeds are very small, and a single plant produced one million and a half by actual count. Owing to the small size of the seeds, they are easily cleaned from grain. The distribution of the plant is almost entirely by the wind blowing the heads across the prairies during the winter.

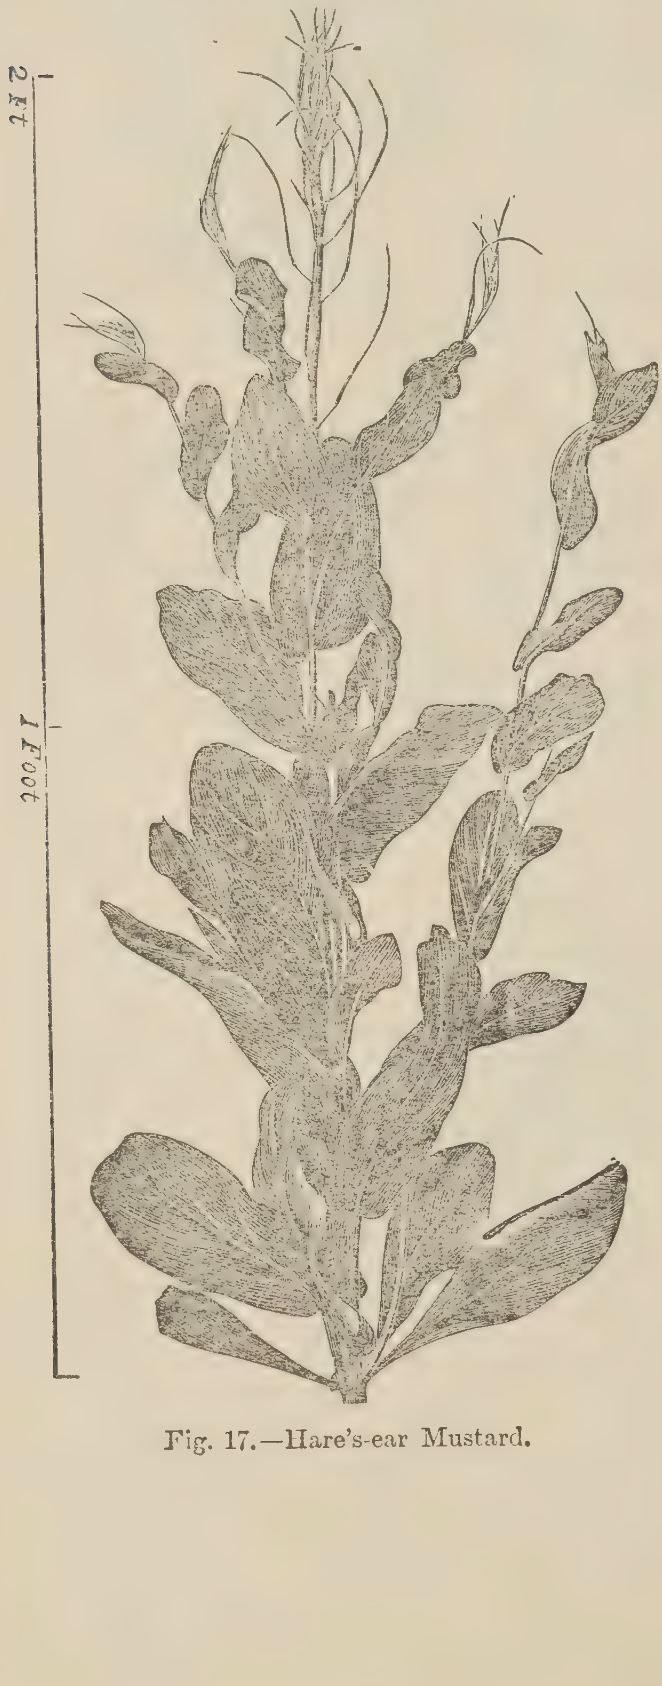

Fig. 17.—Hare's-ear Mustard.

Remedy.—The best means of clearing land of this and other kinds of mustard mentioned below consists of harrowing or cultivating with a weeder the growing crops of grain as long as possible in spring, and subsequently hand-pulling the flowering plants and mowing them down at the edges of fields, on road allowances, railway banks and waste places.

Hare's-ear Mustard [*Conringia orientalis*, (L.) Andrz.].—Annual. Introduced. This is an extremely injurious plant with large leaves, grayish-green, like those of a young cabbage or field pea, but shaped like the ear of a hare or rabbit ; flowers small and creamy white, followed by long square pods from 3 to 4 inches long, a vigorous grower and an absorber of much moisture. The ripe stems, sometimes 4 feet high, are wiry and stiff, and give much trouble when grain is harvested, not only in cutting, but also in binding and handling. The seeds of this plant are much larger than those of the Tumbling Mustard and are frequently found in seed grain, with which they are distributed. The Hare's-ear Mustard now occurs widely through Manitoba and the North-west Territories. Mr. Willing places it third in his list of the worst weeds.

False Flax (*Camelina sativa*, Krantz).—Annual and winter annual. Introduced. A slender-branched plant of the Mustard Family which matures early, the numerous pear-shaped pods containing several seeds. This is widely spread in the West. The chief causes of its increase in the past has been the late date at which summer-fallowing has been done.

FIG. 18.—Ball Mustard.

BALL MUSTARD [*Neslia paniculata* (L.) Desv.].—Annual Introduced. A tall, slender, somewhat branching, orange-flowered plant, with a great number of small single-seeded almost round pods, each one borne on a slender foot-stalk. Like the Tumbling Mustard and the Hare's-ear Mustard, this is a recent introduction into America, but has spread through the wheat-growing districts with alarming rapidity. Mr. Braithwaite says: 'This is a very bad weed as is shown by the way it has spread.' Mr. Willing writes of it: 'Ball Mustard has made more headway in Alberta and Saskatchewan in a given number of years than any introduced weed.'

WILD MUSTARD (*Brassica sinapistrum*, Bois.).—The true Wild Mustard or Charlock, also called Cadluck and Herrick, is not, compared with many others, a common weed in the West. The plant most frequently spoken of there as Wild Mustard is the Bird Rape (*Brassica campestris*, L.). The two plants may be easily distinguished. In Wild Mustard the stems and leaves are rough, the joints of the stems marked with purple, the knotted pods about one inch long on short thick foot-stalks, erect and tipped with an empty or one-seeded two-edged beak. In the Bird Rape the stems and pods are perfectly smooth and glaucous, the pods, which are from $1\frac{1}{2}$ inches to $2\frac{1}{2}$ inches in length, stand out from the stem on slender spreading foot-stalks.

SHEPHERD'S PURSE (*Capsella Bursa-pastoris*, Mœnch).—Annual. Introduced. This plant, like the Stink Weed, is frequently overtaken by winter when in full flower, but is in no way injured, the flowers and pods of the late autumn developing the following spring and producing an early crop of seeds. Few people have paid the attention to this weed in the West, which its noxious character, as it there develops, demands, and as a consequence it is increasing and spreading in an alarming manner, not only in gardens but in wheat fields. Owing to the early date at which the minute seeds develop and the enormous numbers in which these are produced, I fear this weed is going to be a cause of serious loss to western farmers. The plant is easily recognized by its rosette of cut-up leaves lying close to the ground, and bearing from the centre a much branched stem covered from bottom to top with numerous flat triangle-shaped pods. This weed is a close relative of the Stink Weed, and land infested with it should be specially attended to. The seeds are frequently too ripe by the middle of June to allow of their being ploughed down without danger. Summer-fallows should therefore be cultivated or mowed before being ploughed.

LAMB'S QUARTERS (*Chenopodium album*, L.).—Called in different places by several other names, in Manitoba most widely known as Pigweed, also as Fat-hen, Goosefoot and Wild Spinach. Lamb's Quarters, however, is the name used over by far the largest area in Canada, and Pigweed properly belongs to the common Amaranth or Red-root. The Lamb's Quarters, which is an annual plant, of which there are both native and introduced forms, the latter, however, being by far the most abundant in the West, finds in the highly fertile and slightly alkaline soils which prevail there, just such conditions as enable it to develop most luxuriantly, and it is so prevalent in some seasons as to cause a very large loss to farmers, not only in crowding out and robbing the grain while growing, but in every other way reducing the value of the crop by increasing the labour and expense of harvesting, threshing and shipping, and the subsequent and always unpopular dockage for weed seeds by the grain buyer or miller. The Lamb's Quarters prevails to so much greater an extent than any other weed that with some farmers the word 'weeds' means nothing else. It is a succulent annual which does not ripen its

seeds very early in the season; therefore, if land is harrowed before sowing and the grain sown in favourable weather, the crop, as a rule, gets well ahead and keeps the lead over the weeds, so that these do not develop to an injurious extent. In springs when there is cold weather after seeding, the seeds of the hardier weeds germinate more quickly than any of the cultivated grains, and in the constant struggle which goes on throughout the season between a crop and its weed enemies, the one which gets the best start, as a rule, holds the advantage to the end. The farmer is able to help much in this struggle to his own advantage, by using improved methods of farming suited to his own land and the variations of the season.

Remedy.—With annual weeds, the main point to be aimed at is to destroy them as seedlings and as soon as possible after the green seed leaves appear. No weed seedling can spring up on land except from a seed, and, if all weeds can be destroyed by any means before they ripen their seeds, the land, in time, must become clean. The method of harrowing growing grain lately practised in the West with excellent results is, I believe, the cheapest and best means of controlling Lamb's Quarters and all other annual weeds which every year do so much harm in western wheat fields, many of which are so large that no other manner of treating them is practicable.

WILD BUCKWHEAT (*Polygonum Convolvulus*, L.).—Annual. Introduced. In certain seasons this climbing bindweed is a terrible pest in the West, many acres of crop being entirely ruined by it. The seeds ripen very irregularly, some of them before the date at which summer-fallows are generally turned down. Western farmers, however, are wisely summer-fallowing much earlier and oftener than has been the custom in the past, and, although in this way they may increase their labour to the extent of one or even two harrowings, there is no doubt that many weeds will noticeably decrease in abundance, this abundance having been largely due to the frequency with which ripe seeds were ploughed down upon land summer-fallowed after the middle of July. Speaking of the last year or two, Mr. Willing says: 'Wild Buckwheat and Lamb's Quarters are getting away with as large a share of the farmer's profit as any of the weeds which occur here.'

Remedy.—The early and regular summer-fallowing of land every third year. Mr. Braithwaite has tried and strongly recommends a method of treating land infested with Wild Buckwheat. He says: 'I have found that, if an ordinary harrow be turned upside down so that the nuts and the tops of the teeth only protrude, a growing crop of grain may be cleaned of most of the Wild Buckwheat by simply dragging the inverted harrows across it. Of course, if a weeder is used at the right time this will never be necessary, but this weed germinates very quickly and roots deeply. When it has about three leaves, it is very tender and the harrows will break off or pull up millions of plants or check them and give the grain a chance.'

RUSSIAN PIGWEED (*Axyris amarantoides*, L.).—Annual. Introduced. This is a tall coarse-growing plant with a hard woody stem which up to the present has not given much trouble in grain fields but is spreading rapidly in Manitoba and the Territories along railways. Farmers will do well to watch it closely and prevent its increase. It belongs to the same family as the Lamb's Quarters.

COW COCKLE (*Saponaria Vaccaria*, L.).—Called also Soapwort, Cow Herb and China Cockle. A soft succulent annual with pretty pink flowers, belonging to the Pink Family, which was introduced into southern Manitoba from Europe. It has spread with rather alarming rapidity through many parts of the prairie provinces. The seeds are round, hard and black, two or three times as large as those of Wild Mustard, the surface is slightly roughened, a character by which they can be easily distinguished from the seeds of wild vetches, which are of about the same size.

GREAT RAGWEED (*Ambrosia trifida*, L.).—Annual. Native. This is the 'Crownweed' of millers. As an aggressive weed the Great Ragweed seems to be largely con-

fined to the rich lands of the Red River valley. It is a very coarse tall-growing plant, which does not ripen its seeds until late in the season. Summer-fallowing every third year and a little hand pulling during the two crop years will soon clear land of this weed. The Great Ragweed is particularly obnoxious to grain buyers and millers, owing to the difficulty with which its seeds are separated from grain, as they are of about the same size and weight as the grains of wheat and consequently cannot be easily blown or sifted out of wheat.

CANADA FLEABANE (*Erigeron Canadensis*, L.).—Called also Horseweed and incorrectly 'Fireweed.' Annual. Native. A tall wand-like plant with small greenish-white flowers, to be seen with the two common biennials False Tansy (*Artemisia biennis*, Willd.) and Common Evening Primrose (*Œnothera biennis*, L.) upon all summer-fallows. These three plants all of them flower much later than the time when land should be summer-fallowed to get the best results, both for controlling weeds as well as for the more important reason, in the West, of conserving moisture in the ground. The best remedy then for these is to summer-fallow early.

BLUE BUR (*Echinospermum Lappula*, Lehm.).—Annual. Introduced. A weed which has appeared only of late years in the West but has spread very rapidly, owing to its bristly barbed seeds. As a rule this weed is a denizen of waste places and road-sides, but it is gradually working its way into the crops. The seeds ripen about the middle of July; therefore land should be ploughed before that date to prevent the plants from seeding.

Fig. 19. Peppergrass

PEPPERGRASS (*Lepidium apetalum*, Willd.).—Native. Winter annual. A weed which occasionally appears very abundantly, particularly on light land and in wet seasons. For the most part the seeds germinate in the autumn and the seeds are produced the following season. The appearance of the plants in autumn and spring is as flat rosettes of narrow deeply indented leaves lying close to the ground with a single central tap root. Disc-harrowing in autumn and spring is the best treatment of land for this and other plants of a biennial habit.

SKUNK-TAIL GRASS (*Hordeum jubatum*, L.).—This grass is one of the most troublesome weeds in hay. Although it may when young be cut as hay and fed without danger, the hard ripe seeds often cause very painful sores in the mouths of horses and cattle, as they are very sharp-pointed and barbed. They run down by the side of the teeth, or penetrate any soft part of the mouth particularly beneath the tongue and into the tongue itself. There are two distinct forms of this grass, one with long silvery awns, 2 inches long, and another with a more erect habit which has awns little more than half that length. Various methods have been tried to clean hay lands of this troublesome pest, but none with much success. If the Skunk-tail Grass is cut when quite young, it makes tolerably good feed, and hay lands where it occurs should be mowed early before the ripening of this injurious grass. A method of cleaning hay practised at Gladstone, Man., is to toss the hay with a pitch fork on a windy day before using it, when most of the light feathery heads of the Skunk-tail Grass will blow away from the hay and may then be gathered up and destroyed. Whenever this grass is seen in waste places or roadsides it should be mowed before it is ripe and burnt.

This grass is generally described as an annual, but in Manitoba it is certainly a biennial, and apparently sometimes a perennial. It is a bunch grass and has no running root-stocks, growing only from seed.

Native Perennials.

Fig.—20. Indian Hay.

There are a few native perennial plants which are troublesome weeds on farms. Among these may be mentioned the White-stemmed Evening Primrose (*Œnothera albicaulis*, Nutt.), the Spreading Dogbane (*Apocynum androsæmifolium*, L.), the Blue Lettuce (*Lactuca pulchella*, DC.), Skeleton Weed (*Lygodesmia juncea*, Don.), Poverty Weed, or Smotherweed (*Iva axillaris*, Pursh), the Prairie Rose (*Rosa Arkansana*, Porter), and Indian Hay, or Sweet Grass (*Hierochloa borealis*, R. & S.). All of these on account of the difficulty with which they are eradicated have in different districts been stigmatized as 'the worst weed in the country.' They are all deep-rooting perennials with great tenacity of life, and the method which on the whole has given the best results, is to plough deeply in summer after the plants have drawn off a large amount from their supply of reserve material laid up by the leaves in the underground stems during the preceding summer. The broken up root-stocks, however, will still have much vitality, and if left undisturbed will throw out fresh shoots, and the land will be in a worse condition than before. To prevent this, about a month or less after the first ploughing, the land should be disc-harrowed, and this operation should be repeated again a month later, when the root-stocks of most plants will be so far weakened as to be past recovery. A few, however, as the Canada Thistle, Blue Lettuce and Sweet Grass, may require further treatment and the placing of the land under a hoed crop the next year.

Occasional Weeds.

There are every year, probably dependent on the season, certain plants which, appearing suddenly, draw general attention by their abundance over greater or smaller areas. Some of these are of little importance, but others sometimes cause considerable anxiety and loss. Among these may be mentioned the following:—

Wormseed Mustard (*Erysimum cheiranthoides*, L.).—A biennial plant with acrid principles in all its parts, the seeds particularly having caused death in cattle when fed in quantities among other seeds screened from wheat.

Small-flowered Wallflower (*Erysimum parviflorum*, Nutt.).—A native biennial, sometimes abundant in land which has been left without summer-fallowing for too long a period.

Western Wallflower (*Erysimum asperum*, DC.).—Last year one of the most conspicuous plants in some crops in western Manitoba and south-eastern Assiniboia was the beautiful golden-yellow-flowered Western Wallflower, or Prairie Rocket. This is a native biennial very easily pulled from the ground, and, although on account of its brightness it was much noticed, it can hardly be classed as a noxious weed. It very

seldom grows to a large size in crops and is easily killed by autumn or spring cultivation.

YELLOW WHITLOW-GRASS (*Draba nemorosa*, L., var. *a*, *leiocarpa*, Lindl.).—This is a small few-branched winter annual, seldom more than four to six inches high, with few leaves and a great many smooth pods about half an inch in length on slender wide-spreading foot-stalks. The flowers are bright yellow, borne at the ends of the branches. There is no danger, I believe, of this feeble native plant ever becoming an aggressive crop pest, but it was conspicuously abundant on almost every summer-fallow through Manitoba and the North-west Territories last June. At every one of the twenty-one meetings held, specimens were shown or questions were asked about it.

GRAY TANSY MUSTARD (*Sisymbrium incisum*, Englm., var. *Hartwegianum*, Watson).—Native. Biennial. A tall grayish-green slender plant 3 to 4 feet high, very leafy at the base and bearing at the summit a compressed panicle, thickly loaded with short erect pods. The leaves are very finely divided and cut up, from which fact it is sometimes inaccurately spoken of as 'Rag-weed,' a name which belong to quite a different plant. This crucifer was the most striking unusual plant on western wheat fields and summer-fallows last year, attracting the notice of everybody by its tall cones of grayish green leaves standing up above the young grain in June. Mr. Braithwaite writes: 'The Green and Gray Tansy Mustards were very much in evidence this year, but, being natives and biennials, they only showed up on breaking, summer-fallows, or in crops sown on stubble. Our farmers are now understanding the nature of the different kinds of weeds, and will in future control this kind by late fall or spring cultivation.'

GREEN TANSY MUSTARD (*Sisymbrium incisum*, Englm., var. *filipes*, Gray).—Somewhat like the last, but of a bright yellowish-green colour, and without the hoary pubescence, the branches, instead of being close together, spread loosely and form an open head, the seed pods also are borne on slender spreading foot-stalks, and the leaves are much more finely divided. A character which makes this a more dangerous weed than the last, although as yet it is the rarer of the two, is that the seeds ripen very much earlier, so that there is more danger of the ripe seed being ploughed in when land is summer-fallowed.

GOLDEN FUMITORY (*Corydalis aurea*, Willd.).—An occasional weed in Manitoba is this biennial fumitory. While in the East, where it is rather an uncommon plant on rocky banks, the stems seldom exceed 6 inches in length, in the Manitoban wheat fields patches from 2 to 3 feet across are not uncommon, and instances have been reported to me frequently of several acres of crop being choked out by it.

TARRY COCKLE (*Silene antirrhina*, L.).—A plant which could hardly have been suspected of ever developing into an agricultural pest is the slender-stemmed member of the Pink Family, to which the name of Tarry Cockle has been given. This is a plant with an upright stem bearing (in the West) many erect branches, each joint of which has a dark brown sticky patch to which dust and insects adhere. I have seen this occurring in some quantity at different places, and specimens are frequently sent in by farmers for name. Last summer Mr. Braithwaite found large patches of it in crops at Blythe, south of Brandon, in Manitoba, and the Rev. W. A. Burman saw at least 400 acres near Carberry so infested that the weed had almost crowded out all the wheat.

THREE-FLOWERED NIGHTSHADE (*Solanum triflorum*, L.).—Called also Wild Tomato. A native annual plant with deeply indented leaves, and the whitish flowers in umbel-like, three-flowered cluster, followed by green or purplish berries, about as large as small cherries; the whole plant has a musky odour, pleasant at first but afterwards very nauseous. This weed is a coarse decumbent herb forming patches 2 or 3 feet across, and is frequently troublesome in gardens and around the edges of fields.

SPEAR-LEAVED GOOSEFOOT (*Monolepis chenopodioides*, Moq.).—Annual. Native. A dark green succulent plant forming thick patches wherever soil is a little alkaline. Frequently growing so abundantly in root crops and gardens, as well as in wheat fields, as to require much labour to keep it down. The leaves of this plant are borne very thickly on the clustered stems, the lowest ones shaped like the head of a halberd or spear, but those above becoming gradually simpler in outline and smaller. Short seed-bearing spikes occur along almost the whole length of the stems.

WEEDS AND WEEDERS.

The introduction of weeders into the dry regions of the West, I consider an event of enormous importance to all grain growers. During the past five summers I have had exceptional opportunities, in driving through Manitoba and the North-west Territories, of meeting, and seeing the farms of, some of the best farmers in the West. In many places I have met men who made a practice of harrowing their growing grain crops with a light harrow, and invariably with great advantage. Upon the introduction of the various weeders these were used by a few of the most enterprising settlers, and almost always with decided satisfaction. So much was this the case that last spring several carloads of them were shipped into Manitoba by implement makers. The season of 1899, however, was so wet and late that the weeders were not used so much as would ordinarily have been the case. From what I have seen of these implements here, but particularly at the Indian Head and Brandon Experimental Farms, and from what I know to be the condition of the wheat fields in Manitoba and the North-west Territories with regard to annual weeds, I am convinced that there is more to be hoped for in the regular use of these implements after the grain is up, than from any other measure so far suggested for cleaning lands infested by such aggressive and persistent agricultural pests, as Stink Weed and the different kinds of Mustard, as well as all other seedlings growing among grain crops. Weeders can be used not only safely, but with the greatest advantage to a grain crop, from the time the leaf is an inch high until the plants have shot up 6 or even 8 inches.

One of the frequent complaints made against weeders by western farmers is that they cover too narrow a strip of the crop at a time, but in the *Farmer's Advocate* of Winnipeg for December 5, at page 612, is given a cut, which the proprietors have kindly allowed me to use here, showing a successful way of uniting two of these implements and covering 24 feet at once. In this way the writer, W. F. Baker, of Portage la Prairie, states that he can go over nealy 50 acres in a day. The two weeders are fastened together with a rope, and the horses are kept apart by a stick between the halters. The wheat in the fields reported upon, had been cultivated twice after it was 4 inches high, and he says, as has been found by many others to be the case, and as I have myself frequently seen: 'If properly used when weeds are very small, nearly all weeds can be destroyed. On July 18, the wheat thus cultivated was 4 feet high and nicely out in head. The field shown in the cut was 70 acres of the first crop after summer-fallowing. It yielded 1,800 bushels (nearly 26 bushels to an acre), and so far as shipped, graded No. 1 hard. Another 70-acre field, cultivated with the weeder, yielded 29 bushels, while a larger field, that we thought did not require a weeder, yielded only 17 bushels.'

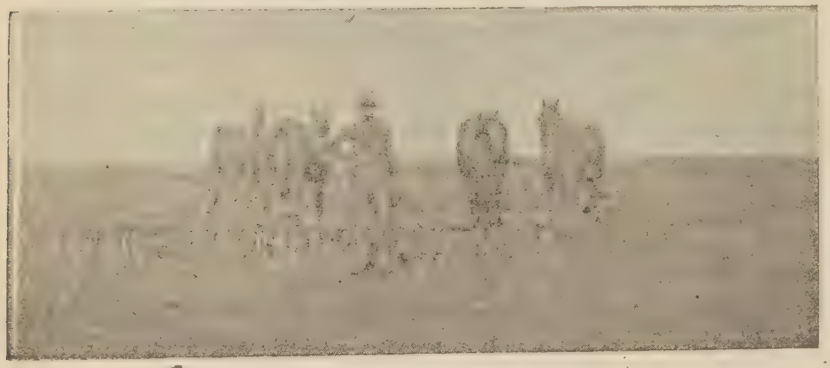

Fig. 21.—Two weeders joined.
(Cut kindly lent by the *Farmer's Advocate.*)

Mr. Angus Mackay, at Indian Head, has the greatest confidence possible in these implements, and last year used them on every acre he had under grain.

There has been considerable inquiry during the past year or two as to the treatment of grain crops infested with mustard, with solutions of sulphate of iron and sulphate of copper. There is no doubt whatever, as I have proved by experiments here and the Rev. W. A. Burman has shown in Manitoba (1898), that the annual mustards can be killed and even Stink Weed, when young, seriously injured by solutions of sulphate of copper, as weak as 2½ pounds to 10 gallons of water. On this subject I would merely point out that, at the very lowest estimate, and using the most economical effective solution yet recommended (2 per cent sulphate of copper*), $1 per acre would be the very lowest estimate at which the cost of this operation could be calculated. In the West where a good many of the farmers work several hundred acres, which they frequently never visit again after the spring work is done, until they turn in the reapers at harvest time, this extra expense including the purchase of spraying pumps and sulphate of copper, and the extra work of drawing water, and mixing and applying the solution, would be far less advantageous or likely to be practised, than the use of weeders or light harrows, which most certainly is better farming; for this operation, besides doing better work in destroying the seedlings of all kinds of weeds, has been proved to be most beneficial to the growing crops by reason of the extra cultivation thus given to the land at the very time when it requires it, and the fields so treated yield much heavier crops.

Mr. Charles Braithwaite, who has had greater opportunities of forming an opinion on this matter than any other man in Manitoba, replies as follows to an inquiry as to the utility of surface cultivation of growing grain crops :—

'PORTAGE LA PRAIRIE, Oct. 9, 1899.—I may say that, from my own observations, in ordinary years I certainly agree with your opinion. Working growing grain with light harrows or weeders has a twofold advantage: it destroys weeds and also creates a mulch which prevents moisture from evaporating. Of course, this year being a moist year, the work could not be done as effectually as in drier years. During the season of 1898, Mr. Henry Nichol, of Brandon, had two weeders and kept them going until the grain was 5 and 6 inches high. His crop averaged 30 bushels per acre, while his neighbour's did not average over 15 bushels, and some within 5 miles of him had to plough up their crop on account of weeds and drought. I had this from Mr. Nichol himself, and he is, as you know, a thoroughly reliable man. I could tell you of scores of others who have saved their crops by this method. Of course, as I tell the farmers, this surface cultivation of grain with any kind of implement must be done with common sense, not too deep nor too shallow, and, when the land is in proper condition for harrowing, not too wet and not too dry.'

THE WHEAT CROP IN MANITOBA IN 1899.

The wheat crop in Manitoba in 1899 has been estimated at 27,000,000 bushels, almost all of excellent quality and exceptionally free from weed seeds. This satisfactory result is due chiefly to the season. The late date at which severe frosts occurred allowed almost the whole crop to be got in without injury, and the freedom from weeds was due largely to abundant moisture last spring and the previous autumn. On account of cool wet weather last spring, seeding of wheat was much delayed, but the seeds of many weeds being in the ground germinated quickly and came up in the first warm days. Enormous numbers of these seedlings were destroyed at the time the grain was sown; thus the land was clean of all the weeds that had germinated, and the wheat being put in under the most favourable circumstances, germinated promptly and got ahead of the weeds. In addition to the benefit due to the wet spring of 1899, the exceptionally wet autumn of 1898 was also very beneficial by causing many of the seeds of annual weeds to germinate before winter set in, so that they were destroyed by frost These, under the usual climatic conditions which prevail in ordinary years in Manitoba and the West, do not, for lack of moisture, germinate before the following spring. As a

* See article by Mr. Shutt, page 194.

consequence of the above mentioned circumstances, the fields were exceptionally clear of weeds last spring, a satisfactory state of affairs which lasted until the end of the season.

The following extracts from letters of men who can speak with authority illustrate this point.

Mr. H. McKellar, who as Chief Clerk of the Department of Agriculture meets farmers from all parts of the province and receives reports throughout the season on the condition of the crops, says as follows :—'I have made reference on two or three previous occasions to the absence of weed seeds in this year's crop. The fact that the grain is much cleaner this year than it has been for several years is commented upon by everyone who handles grain. In fact, I might say that this year one hears nothing about dockage for weed seeds. This merely bears out the excellent appearance of the fields which we noticed in driving through them together last June and July.'

Mr. Charles Braithwaite, who as Provincial Weed Inspector travels continously over the province, inspecting crops and advising farmers how best to treat their land and avoid loss from weeds, writes : 'This is without exception the cleanest crop the West ever reaped. The climatic conditions were favourable ; last summer and fall there was moisture enough to germinate weed seeds, and then again this last spring there was a good growth of weeds before the land was fit to seed. The weeds germinated and and were destroyed in the cultivation at seeding time, and the grain came right away.'

The following report is from Mr. G. H. Greig, of the *Farmer's Advocate*, who has good opportunities of judging :—

'Winnipeg, Oct. 11—The crop generally speaking through Manitoba and the West is very much cleaner and freer of weeds than it has been for some years. The assumption is that, owing to the excessive moisture in the soil last spring, seeding was not started as early as usual, and consequently a great many weed seeds would germinate before any cultivation was given the land ; the seedlings were afterwards killed by the cultivation at seeding time. At all events, the season has not been favourable to weed growth, and crops are cleaner than they have been for years. No doubt, very much credit for this desirable state of affairs is due to the excellent work done by local department of agriculture in holding meetings during the past three years, at which the nature of weeds and the best way to fight them were explained.'

The following report by Mr. F. T. Shutt, Chief Chemist to the Dominion Experimental Farms, will be read with interest by those seeking information as to the remedial treatment of mustard with sulphate of copper and sulphate of iron. The application of these solutions may be found useful in small areas in the East or in British Columbia, but is not a practical nor advisable method to recommend on the large farms in the drier regions of the West.

SPRAYING FOR DESTRUCTION OF MUSTARD.

By Frank T. Shutt, M.A., Chemist, Dominion Experimental Farms.

One of the most persistent weeds that farmers in many parts of Canada have to contend with is mustard, commonly known in Europe as Charlock. Though an annual, it is most difficult to eradicate from fields in which it has become established, owing to the fact that the seed—of which a large number is formed—are endowed with a strong vitality and are preserved from decay by the oil they contain, until favourable conditions for sprouting occur.

Pulling the mustard when it appears among the grain, or keeping the weed from seeding by working the land (as under a hoed crop), are the two methods which have hitherto been in vogue to exterminate this pest, and when the work is done thoroughly they may be considered satisfactory and efficient. The former, however, is always costly, and the latter is sometimes not convenient. When, therefore, it was announced in the agricultural press that spraying with certain solutions of sulphate of iron and

sulphate of copper had been tried successfully in England and France, it was deemed advisable to make similar experiments here. We should then be in a position to furnish information at first hand on this subject.

The fields of the Experimental Farm being free from this weed, it became necessary to make the trials upon an adjoining farm, and for that purpose a field of barley was selected which showed a considerable amount of mustard. The size of the plot treated in each case was one-tenth of an acre, and the quantity of solution uniformly supplied to each area was 5 gallons, or at the rate of 50 gallons per acre. The date of spraying was June 26, the grain being 15 inches to 20 inches high, and the mustard practically the same height and just coming into flower. The chief data may be briefly stated as follows :—

Sulphate of Iron; 5 per cent.—No effect upon barley. The leaves were practically all stripped from the stems of the mustard, but the weed was not killed, as evidenced by new leaves subsequently starting the plant flowering and the seed-pods filling out and maturing. The leafless stems were quite green a fortnight after the spraying, and were apparently furnishing nourishment to the seed.

Sulphate of Iron, 10 per cent.—A slight scorching of some of the leaves of the barley was to be noticed. A fortnight after the spraying this was not discernible, and, though this spray may have *slightly* retarded growth, it is not probable that the yield of grain was affected.

Though the effect upon the mustard was more pronounced than in the foregoing instance, as noticed by the 'spotting' on the stems, it was not sufficiently strong to prevent flowering and the ripening of the seeds, a large proportion of which proved, upon testing, to be vital.

Sulphate of Copper, 2 per cent.—A certain amount of injury to the leaves of the barley resulted, evidently retarding growth to a somewhat greater degree than the 10 per cent iron sulphate solution. At the end of two weeks, however, this effect had practically all disappeared, and it became doubtful if there were any permanent injury to the grain. The mustard very quickly showed the effect of the spraying, both the stems and the leaves dying without allowing the plant to seed. Two weeks after spraying, a few living mustard plants were found in the plot, but it is believed they had escaped the solution, owing to the height and overshadowing of the barley.

Sulphate of Copper, 5 per cent.—This solution damaged the barley in a much more pronounced manner than the preceding solution ; in all probability it somewhat lessened the yield of grain, though, as the ground was very uneven in character, no comparative data on this point could be obtained.

The mustard was all killed ; an inspection two weeks after the spraying did not reveal any living plants.

In order to ascertain the effect of these solutions upon this weed at a younger stage of growth than that just reported upon, mustard seed was sown in rows in a plot upon the Experimental Farm. When the mustard plants had reached the height of 6 to 9 inches they were sprayed as follows :—

July 20 : *Sulphate of Iron, 5 per cent.*—Not all killed ; the few survivors possessed green stems and in time sent out new leaves. It is extremely doubtful, however, if the plants will have sufficient strength to flower.

Sulphate of Copper, 2 per cent.—All the plants died within a few days.

July 22.—Further sprayings were made : *Sulphate of Iron*, 5 per cent. The stems were stripped of all their leaves, but in the course of a few weeks fresh leaves had appeared on many of the plants. *Sulphate of Iron*, 10 per cent : Though somewhat more severely attacked than by the 5 per cent solution, there was sufficient vigour left in many of the plants to send out new leaves after a few weeks.

Sulphate of Copper, 2 per cent: Only a very few of the older and more vigorous plants escaped destruction, probably not more than three to five per cent. This solution is evidently strong enough to kill all mustard plants 6 inches in height and less.

Sulphate of Copper, 5 per cent.—All the plants killed.

From the above data, I make the following inferences:—

1. That a two per cent solution of sulphate of copper (that is, 2 pounds in 10 gallons of water) is, all things considered, the most effective, safest (as regards the grain crop) and most economical to use. The spraying should be done thoroughly, and for that purpose 50 gallons per acre will be required. If a heavy rain follows the spraying within 24 hours, the operation will have to be repeated.

2. That, in order that the work may be effective, spraying should not be delayed after the mustard plants have reached a height of 6 to 9 inches. If allowed to grow taller than this, stronger solutions would be necessary and in larger quantity, as the grain would then largely protect the mustard.

NOTES ON LECTURING TOURS IN MANITOBA, THE NORTH-WEST TERRITORIES AND BRITISH COLUMBIA IN 1899.

By instruction of the Honourable Minister of Agriculture and at the request of the several governments of Manitoba, the North-west Territories and British Columbia, I left Ottawa in June last to hold three series of farmers' meetings in the West. The subjects of the addresses delivered were chiefly as follows: In Manitoba, locusts and weeds; in the Territories, weeds and their eradication, special mention being made of the value of summer-fallowing and the use of the implements known as weeders, and nature studies and agricultural education in schools; in British Columbia, the value of Farmers' Institutes, weeds and their eradication, insects injurious to fruits, hay and pasture grasses.

Leaving Ottawa on June 10, I reached Manitoba on the 13th. Passing along the railway between Ottawa and Manitoba, the backwardness of the season was remarkably apparent. Spring flowers which had been in bloom at Ottawa a month earlier, were only now opening their buds. This lateness was also a feature of the season all through Manitoba and the Territories.

MANITOBA.

Upon reaching Winnipeg, I made an examination of the shade trees, which are such an attractive feature of this beautiful city, and found that the Ash-leaved Maples were infested by three different insects: (1.) the Negundo Plant-louse (*Chaitophorus negundinis*, Thom.), (2.) the Cankerworm (*Anisopteryx pometaria*, Harr.)—both of these although much less abundant than in former years, still required attention—and, lastly but much more conspicuous, (3.) the Fleshy Leaf-gall of the Negundo. This is a fleshy swelling on the mid ribs of the young leaves which disfigures them very much. The galls are about an inch in length and contain several yellowish larvæ of a small gnat probably belonging to the genus *Diplosis*. An article was prepared for the press under the caption of 'Spray the Trees,' which was published in the local newspapers, and many availed themselves of the advice given therein.

On June 13 I reported myself at the Provincial Department of Agriculture, and, having been joined by Prof. Otto Lugger, the State Entomologist of Minnesota, I left Winnipeg on the 14th, and with Mr. Hugh McKellar, the Chief Clerk of the Provincial Department of Agriculture, who had made arrangements for an investigation of the areas in southern Manitoba, which were infested by the Rocky Mountain Locust in 1898. We reached Boissevain on the evening of the 14th and held a well attended meeting of farmers the same evening. The first

Fig. 22.—The Rocky Mountain Locust.

address was delivered by Mr. McKellar, who explained what steps had been taken by the Honourable Thomas Greenway with a view to assist the farmers to avoid loss by locusts, which were so abundant in 1898 as to have caused considerable anxiety, and, as none of the observers who had been on the lookout for the egg-laying females last autumn had succeeded in observing any, the hope had been expressed that there would be no locusts this year. The department, however, feared that this was too hopeful a view of the matter, and, on account of the gravity of the case, the Minister had requested the Dominion Entomologist and the State Entomologist of Minnesota to visit the district and examine whether there was any probability of an outbreak of locusts in 1899. Reports had been received that the insects had begun to appear south of Boissevain and Deloraine, and, although the date at that time was three weeks later than when the locusts had appeared last year, it was considered wiser to have the matter investigated carefully, so that, if locusts were found, farmers might be visited and urged to use the methods of destroying the insects which had been found useful elsewhere.

I then followed with a statement of all that was known of the Manitoba occurrences of the Rocky Mountain Locust, the extent of the losses which might accrue if farmers did not adopt the simple and inexpensive means of controlling them which had been advised. Prof. Lugger explained in a lucid manner the life history of this locust, which he illustrated with some large and original charts and gave the results of his long experience in fighting locusts in Minnesota and Dakota. The measures advised were practically those which had already been made known widely through newspapers, agricultural journals and government reports, and were briefly as follows :—The ploughing down in autumn and spring of all stubble in the districts where locusts had been seen, the ploughing down of the young locusts with the stubble as soon as possible after they hatched, beginning at the outsides of fields and working towards the centre ; wherever the young had hatched and made considered growth before the stubble was ploughed down, the use of the hopper-dozers, and on restricted areas the poisoning of the insects with arsenical mixtures.

Mr. Charles Braithwaite, the Provincial Weed Inspector, was also present and spoke at this meeting ; he also accompanied us through the rest of our investigation, in which he was of much assistance.

Fig. 23.—Messrs. Fletcher, Lugger and McKellar finding locusts' eggs.

On the morning of the 15th we started early and drove down to the beautiful farm of Mr. A. S. Barton, and thence to Mr. Frank Thompson's, where the exact localities could be pointed out in which the locusts had occurred the previous year. No trace of the insects or their eggs was found; indeed, there was, both here and during a 25-mile drive to Deloraine, a most remarkable absence of all kinds of locusts or 'grasshoppers,' the name by which they are generally spoken of in the West. On reaching Deloraine, we were met by Mr. John Renton, of that place, and Mr. Thompson, of Waskada, who told us that hoppers had been seen on the hatching grounds six miles south of Deloraine, where I had found them last year. Accordingly, we drove to these farms, where they had been most abundant, and made a thorough search for the eggs. We soon saw that young locusts were hatching in large numbers, some were just emerging from the eggs, and some unhatched ; many egg-pods also were empty, but showed that the eggs had been destroyed by parasites. The egg-pods were about an inch below the surface, mostly on elevated spots, and on the sunny side of furrows on these elevated spots. This date of hatching (June 15) was fully three weeks later than that at which the young grasshoppers must have hatched last year, for I found fully matured insects on July 4, 1898. This was due to the late wet spring, a circumstance which also was of great benefit to farmers by making it easier for them to control weeds.

On the evening of the 15th a meeting was held at Deloraine, which was wel attended by farmers from the surrounding country, and addresses were delivered similar to those given at the Boissevain meeting, except that we were now able to speak strongly and definitely as to what steps it was advisable for the farmers to adopt without delay. At this meeting Mr. D. S. McLeod brought specimens of locusts from Lennox, only a few miles south-west of the Deloraine occurrence; these were apparently a week or more older than any we had seen in the fields we visited. At this meeting Prof. Lugger gave the chief address of the evening, describing in detail the best means to adopt under the present conditions to prevent the spread of the swarms now hatching; he also showed plans and explained thoroughly the construction of hopper-dozers, in case these implements should be required later in the season. From what we had seen, however, we were able to encourage the farmers to hope that, if all would plough down the stubbles left for summer-fallowing at once, the locusts might be prevented from spreading and causing serious loss.

After the Deloraine meeting we left for Napinka and took the early morning train to Brandon, where a profitable morning was spent examining the magnificent crops on the Brandon Experimental Farm. The Awnless or Smooth Brome Grass, the introduction of which by the Experimental Farms has been such an immense boon to the farmers of the West, was at that time (June 16) just spearing, and the meadows were a thick mat of grass, over two feet in height. In the afternoon a good opportunity of meeting many of the best farmers of the province was afforded at the ploughing match of the Blythe Farmers' Institute, held near the Brandon Hills Post Office. Here we were again invited to deliver addresses on our grasshopper investigations, a subject which proved of much interest to the hundreds of farmers present. We returned to Brandon in the evening, and on the morning of the 17th I separated from my very pleasant companions.

Owing to the excellent arrangements made by Mr. McKellar and by the generosity of the Northern Pacific and Canadian Pacific Railways who had given the whole party free transportation over their lines, we had been able in a very short time to travel a long distance and also to meet the farmers most keenly interested in the locust occurrences. That the farmers of southern Manitoba appreciated the efforts of the governments to help them, is attested by the following letter received from Mr. McKellar at the end of the season:—

'There is no doubt but that your visits to Manitoba in 1898 and June 1899, examining the Deloraine district, invaded by grasshoppers, did much good. Farmers were interested in the definite information given by you regarding the habits of the grasshoppers and the best methods for fighting them. Instructions *in re* fall ploughing or early spring ploughing and early summer-fallowing have been followed. A few farmers have used hopper-dozers this season, and if necessary, more will be used the coming year. The injury done in 1899 was not appreciable. The crops were of very heavy growth, and the harm done, therefore, not so evident. There has been more fall ploughing in the Deloraine, Whitewater and Boissevain districts last fall than in any previous year. This was partly on account of the very favourable fall, but farmers were no doubt stirred up to the work by the knowledge that they were taking the best means possible for destroying the eggs of grasshoppers that might have been deposited during the summer.'

North-West Territories.

June 18 was spent in answering correspondence which had been forwarded to me from my office at Ottawa, and on the afternoon of the 19th I left for the West, reaching Moosomin at 4 o'clock, in time to join the Honourable G. H. V. Bulyea, the Commissioner of Agriculture for the North-west Territories, and hold an afternoon meeting of farmers; this was the first of a series of seventeen meetings held in the southeast of Assiniboia. These meetings were arranged by the Commissioner to be held at the points where it was considered good work could be done by explaining to farmers living in that magnificent and fertile section: (1) the exact meaning of the North-west Noxious Weed

Ordinance and the attitude of the Provincial Government on the subject; (2) the nature of noxious weeds, the danger of many varieties being introduced from the East; and giving a detailed description of the kinds most to be feared in each locality, with the best means of eradicating or fighting against them. The order of the meetings was as follows: The Commissioner, who was present at almost every meeting, opened with an exposition of the Weed Ordinance; I followed with a treatment of the subject of weeds and their eradication, illustrating my remarks with fresh specimens of the worst weeds to be found in each locality, either brought in by farmers or collected before the meeting. There were also shown prepared specimens of those not yet introduced but which were to be feared and which might appear at any time among crops. At most of these meetings we were accompanied by, and received much assistance from, Mr. Wm. Trant, of Regina, who not only took an active part in the meetings but prepared careful accounts of each for the press, in which the chief features of the addresses were presented in an excellent manner. Some of these meetings were also rendered much more attractive and useful by the presence and timely addresses of the active Deputy Commissioner of Agriculture, Mr. C. W. Peterson, and the Territorial Weed Inspector, Mr. T. N. Willing, who is both an expert botanist and also a practical farmer who has lived for many years in the West. It will be seen by the list of places given below where meetings were held, that a large area of country was visited, the exceptional fertility of which was clearly proved by the prosperity of the farmers, as evidenced by the fine houses and buildings and the well-kept farms.

At Regina we were honoured by the presence of His Honour the Lieutenant Governor of the North-west Territories, the Honourable A. E. Forget, who took an active part in the proceedings.

The series of meetings began at Moosomin on the 19th and ended at Gainsborough on July 7. They were convened through the different agricultural societies, and in every instance an officer of the local society presided. The enthusiastic welcome accorded the Honourable Commissioner and the keen interest shown in the subject as evinced by the large attendance at all the meetings, and the animated discussions, were very gratifying. The numbers which were present were remarkably large considering the distance most had to travel, and the fact that it was necessary to hold these meetings at a very busy time of the year for farmers.

The following is a complete list of the meetings held, with the name of the chairmen:

Date.	Place.	Chairman.		
1899.				
June 19	Moosomin	J. M. L. Young, President, Agricultural Society.		
" 20	Whitewood	R. Nicholson,	"	"
" 21	Grenfell	R. D. Lake, M.L.A.,	"	"
" 22	Wolseley	Dr. Elliott, M.L.A.,	"	"
" 23	Indian Head	Angus Mackay,	"	"
" 24	Qu'Appelle	W. H. Henley,	"	"
" 26	Fort Qu'Appelle	A. Macdonald,	"	"
" 27	Regina	G. Spring-Rice,	"	"
" 28	Moose Jaw	Jno. Battle,	"	"
" 29	Fairmede	J. Clementson,	"	"
" 30	Glen Adelaide	Wm. Piggott,	"	"
July 1	Clare	J. L. Thompson,	"	"
" 3	Carlyle	Jno. Stewart,	"	"
" 4	Alameda	S. Miller,	"	"
" 5	Oxbow	D. W. Maitland, Secretary,		"
" 6	Carnduff	Jno. Young,	"	"
" 7	Gainsborough	Wm. Taylor, President,		"

After the Moosomin meeting we went by freight train to Whitewood, arriving there early in the morning of the 20th. The morning was spent in collecting plants

with Mr. T. N Willing. We took the evening train for Grenfell, where we were met by Mr. R. D. Lake, through whose kindness I was driven out to his home and had an opportunity of seeing the nature of the country and its condition as to the prevalence of weeds. The following morning further opportunities were afforded by a 15-mile drive round by the farm of Mr. T. Skilliter and back to Grenfell, where a very largely attended meeting was held, one of the best of the whole series. After the meeting I returned with Mr. Lake to Col. Lake's house, and the following morning was driven to Wolseley, where we held another good meeting in the new Court House. At Whitewood we were joined by Mr. F. Blakely, of the *Nor'-West Farmer*, who remained with us for all the subsequent meetings but the last. Owing to the much greater altitude, the crops from Moosomin to Grenfell and Wolseley were not nearly so forward as in Manitoba. Winnipeg is about 700 feet above sea level, while Grenfell is nearly 2,000. All crops, however, were in splendid condition and there was every prospect of an enormous yield, the land being, as a rule, clean and well worked.

We reached Indian Head on June 23, when I was met at the station and driven out to the Experimental Farm by Mr. Angus Mackay. During the morning the whole of our party was driven round the farm. Crops of all kinds were in the best of order, and a remarkable object lesson was here seen of the very great value of using harrows and weeders upon growing grain crops. These as a whole were much more advanced than at Grenfell, and those which had been harrowed showed this fact plainly by their greater vigour. The meeting in Indian Head in the afternoon was well attended, and, as was to be expected, summer-fallowing and the surface treatment of growing grain were much discussed. Mr. Mackay has probably taken a more active part than anyone else in the North-west in insisting upon the necessity of a proper system of summer-fallowing for the dry regions of the West, and, as a remarkable confirmation of the accuracy of his views, lands which ten or fifteen years ago were abandoned because it was stated they were too far west and too dry to produce paying crops of wheat, are at the present time selling at a higher price than any other lands in the North-west Territories.

On the morning of the 24th Mr. Mackay kindly drove me himself to Qu'Appelle station and on the way pointed out many features of agricultural interest. The meeting was held in the afternoon, and, like the next one at Fort Qu'Appelle on the following Monday, was particularly well attended, the large number of questions asked and free discussion of the addresses being noticeable features in both places.

On Monday morning June 26, through the kindness of Mr. Donald McKay, I was driven to Fort Qu'Appelle and had a chance to examine many growing crops on the way. This locality was of particular interest because it was from here that the first reports were received of the occurrence as crop pests of the Tumbling Mustard and Hare's-ear Mustard. After the meeting at Fort Qu'Appelle, I drove back to Qu'Appelle Station with Deputy Commissioner of Agriculture Peterson and Mr. Blakely through a torrent of rain and took the train at 20.20 o'clock for Regina.

The following morning was taken up by examining the barracks of the North-west Mounted Police and the successful experiments in cultivating trees and growing flowers which have been carried on for many years by Col. Herchmer. It is very seldom that one can see anywhere such beautiful sweet peas and other annuals, and as well grown vegetables as are produced at Regina in these grounds. A most successful meeting took place in the afternoon at which many prosperous farmers from the surrounding country, as well as several government officials, were present. A vote of thanks to the speakers was proposed by His Honour the Lieutenant Governor, and seconded by Mr. D. J. Goggin, the Superintendent of Education.

The next meeting was at Moose Jaw, and I was much pleased to have an opportunity of driving out both in the morning and in the afternoon to see the grand crops which are now being grown in this semi-arid district, and are due to the recent adoption of the best methods of farming for that section of country. The discussion at the meetnig held in the afternoon was mainly upon the treatment of such annual weeds as the various kinds of mustard, several of which were prevalent through the district, the Spear-leaved Goosefoot (*Monolepis chenopodioides*, Moq.) and of such deep-rooted perennials as the White-stemmed Evening Primrose, Poverty Weed (*Iva axillaris*, Pursh),

known here under the appropriate name of Smother Weed, and the Blue Lettuce (*Lactuca pulchella*, DC.).

Early on the morning of June 29 I left Moose Jaw with Mr. Blakely, and having been joined at Regina by the Hon. Mr. Bulyea, went on to Wapella, where a team was in readiness to take us to Fairmede, 18 miles distant, at which place we held the first of several successful meetings away from the railway, driving from place to place through the country. We were all much surprised at the fine agricultural hall and buildings at Fairmede, but this was soon explained by the prosperity of the farmers in this fertile district. We spent the night at the comfortable home of Mr. John Kidd, who moved out west from the Ottawa district many years ago.

The next meeting was at Glen Adelaide, 22 miles distant, and was reached after a delightful prairie drive in the afternoon. We spent the night at Cannington Manor, and leaving the next morning, were driven by Mr. McDiarmid, M.L.A., through the Moose Mountains and White Bear's Reserve, passing by Heart Hill, one of the highest mounds of these hills, to Arcola (16 miles), where we were hospitably entertained by Mr. J. L. Thompson. Mr. Thompson's farm lies at the foot of the Moose Mountains, with a magnificent stretch of level and extremely fertile land lying to the south of it. The prosperity of this section is clearly shown by the fine houses of the settlers, notwithstanding the long distance over which all produce has to be driven to market or to the railways. In the afternoon Mr. Thompson drove us 7 miles to the new village of Clare, where a meeting was held. A few farms in this district were found to be infested with Stink Weed (*Thlaspi arvense*, L.) and Hare's-ear Mustard [*Conringia orientalis*, (L.) Andrz.], which had been accidently introduced a year or two before, but which had been recognized and were being attended to. The Shepherd's Purse (*Capsella Bursa-pastoris*, Mœnch) and the Green Tansy Mustard (*Sisymbrium incisum*, Engelm., var *filipes*, Gray.) were also remarkably abundant in one or two places, and both plants were seen to be loaded with seeds. At the meeting stress was laid upon the importance of early summer-fallowing and of mowing down all weeds with ripe seeds before the summer-fallows are turned down. We afterwards drove back to Arcola with Mr. Thompson and remained with him until the morning of Monday, July 3.

Leaving at 8 o'clock on July 3, we drove 10 miles to Carlyle, where a large meeting was held in the afternoon, and subsequently 23 miles further to Alameda, on the Souris Branch of the Canadian Pacific Railway, where we were joined by Mr. Trant, and a splendid meeting took place in the afternoon, at which a great number of specimens were brought in by farmers and where there was a most useful discussion. After this meeting we walked to Oxbow, the next station along the railway, passing through the rich lands lying along the Souris River. As we neared the town of Oxbow, we found some crops of wheat in which the Prairie Rocket (*Erysimum asperum*, DC.) was very abundant, and, being such a conspicuous plant, it had naturally caused considerable anxiety among farmers who had recognized it as a member of the Mustard Family. This plant, however, is a biennial which seldom shows itself as abundantly as was the case this year, being a native plant which has never proved to be an aggressive crop pest and which besides is easily pulled up, the large plants never growing very closely together; it is not likely, therefore, to develop into a bad weed.

The meeting at Oxbow was equally successful with the preceding one. The next morning we drove to Carnduff, where we were joined by Mr. T. N. Willing. The farmers here were found to be much interested in the weed question, and the same was the case at the meeting held on July 7 at Gainsborough, many pertinent questions being asked and much interest being taken in the Hon. Mr. Bulyea's efforts to assist the farmers. From Gainsborough a 25-mile drive brought us to Melita on the evening of July 7. Here I finished my work for the North-west Government—three weeks of delightful travelling, in which a large tract of country quite new to me was traversed and in which I had enjoyed many opportunities of studying the insects and plants of the country passed through. I must here express my gratitude to the Hon. Mr. Bulyea for frequent modifications in his plans, which I know were made entirely on my account, so that I might see as much as possible of this interesting country and have every convenience to collect plants and insects, noxious and beneficial.

Manitoba.

On July 8, in accordance with an agreement with the Manitoba Government, I went to Elkhorn, Man. and addressed a meeting of the Elkhorn Farmers' Institute. I remained at this place till the following day, when I took the train back to Winnipeg to assist in the arrangement of the exhibit of the noxious weeds of Manitoba, shown in the Weed Tent of the Provincial Government of Manitoba at the summer Industrial Fair. This exhibit was an unqualified success. Almost every kind of the noxious weeds of the province was shown, plainly labelled with its English and scientific names, and at all times of the day some officials of the department were in attendance to give such information as might be desired by the thousands of farmers who visited the exhibit every day from early morning till late at night.

British Columbia.

On the morning of July 13, I left Winnipeg and proceeded westward to British Columbia by way of the Crow's Nest Pass, visiting the thriving and active towns of Nelson and Rossland on the way. I reached Vancouver on July 19, when I joined Mr. J. R. Anderson, the Deputy Minister of Agriculture for British Columbia. The afternoon was spent in admiring the colossal trees and other plants in Stanley Park. On the morning of the 20th New Westminster was visited, and we reached Victoria the same evening. The 21st was spent in the Department of Agriculture, examining the collections and answering correspondence forwarded from Ottawa. In the evening we went out by special train to South Saanich, where a largely attended meeting of the Victoria Farmers' Institute was held ; the subjects treated of at this meeting were weeds of the farm and injurious insects. We returned to Victoria the same night, and on the morning of July 22 left for Duncan's, on the Esquimalt and Nanaimo Railway. We were met at the station by Mr. G. H. Hadwen and driven out to his fruit farm. We returned to Duncan's for a meeting of the Farmers' Institute held in the afternoon. The subject of main interest at this meeting was Hay and Pasture Grasses. Noxious Weeds and Agricultural Education were also discussed at some length. After the meeting a visit was paid to the grounds of Mr. W. C. Duncan to examine a patch, which he had had under cultivation for many years, of *Bromus virens*, Buckl. (*B. Hookerianus*, Thurb.), a grass of much promise closely resembling the Southern Brome grass (*Bromus Schraderi*, Kunth). We returned by the evening train to Langford and drove to a meeting of the Metchosin Farmers' Institute. This meeting had been well advertised and was largely attended. After the meeting we drove back to Victoria reaching there at 1.30 a.m.

On Monday morning, July 24, in company with Mr. Anderson, I started for the interior of Vancouver Island ; we arrived at Nanaimo about noon and were joined by the Rev. G. W. Taylor, of that place. After lunch we drove 36 miles to Mr. R. F. Hickey's, at French Creek, and later in the evening back to McCarter's Hotel, where an evening meeting was held. This day's journey was full of interest on account of the wonderful forests with which this part of the island is clothed. Objects of great wonder were the enormous trees of *Arbutus Menziesii*, Pursh, many of them over 2 feet in diameter and some large specimens reaching even 3 feet. The next morning we started at 6 o'clock and drove 30 miles to Alberni, arriving there at 3 o'clock in the afternoon.

The drive past Cameron Lake and around the foot of Mount Arrowsmith is one of the most remarkable drives I have ever taken—the road magnificent, smooth and well gravelled the whole way, and through a most wonderful forest, a tract of two miles just past Cameron Lake on the Alberni side, particularly shows the Vancouver Island forests in perfection : gigantic Douglas Spruces, Hemlocks and Cedars—specimens of these trees from 6 to 8 feet in diameter being found by thousands—growing so close together, only 30 or 40 feet apart, that the straight trunks rise up over 100 feet before a branch is reached. The heads of these giants seem very small compared with their towering trunks. The undergrowth beneath these trees is remarkably sparse and consist almost entirely of mosses and ferns, with the beautiful and fragrant *Achlys triphylla*,

DC. The woods the whole way are characteristically mountain woods. The Salmon Berry (*Rubus spectabilis*, Pursh) with its luscious fruit, like enormous orange or maroon-coloured raspberries, was in full fruit, also the Red-berried Vaccinium (*V. parvifolium*, Smith), a most beautiful shrub with bright red fruit like yew-berries, borne singly and produced in such quantities as to bend down the slender branches. A noticeable feature along the road was that many introduced grasses and weeds were abundant which had been brought in either by the road-makers or in carrying hay over the road.

A meeting was held at Alberni in the evening and the following morning we started at 4.30 and drove back 30 miles to Little Qualicum, where we caught the steamer *Thistle* and went to Comox, reaching there at five o'clock in the afternoon. Thence we proceeded at once to Courtney, where we passed the night. The next morning an interesting drive was taken to the mining town of Union and to a beautiful lake three miles beyond. The heat was excessive, but a good meeting was held in the evening, the addresses being followed by animated discussions, the so-called Canada Thistle being the principal subject.

On the morning of July 28 we left by the 7.30 steamboat and reached Nanaimo at five o'clock in the afternoon and started at once with the Rev. G. W. Taylor for Cedars, where a small but enthusiastic meeting was held in the evening. We then returned to Nanaimo for the night. A meeting was to have been held at Salt Spring Island on Saturday the 29th, but we found that the steamboat had been taken off for some excursion, and it was impossible for us to reach the island. We therefore returned to Victoria and remained there until Sunday night, when we took the eleven o'clock steamboat for the mainland. Vancouver was reached by eight o'clock and New Westminster at eleven; we then took the steamer for Ladner's Landing, where our first meeting on the mainland had been advertised. Leaving Ladner's at five o'clock the next morning, we drove back and took the steamer opposite New Westminster for Langley. A good meeting was held in the afternoon, after which we proceeded by canoe to Port Haney and from that place walked to Hammond, where we passed the night. The next morning we took train for Abbotsford, where an informal meeting of farmers was held. In the evening we returned to Mission Junction, and the meeting at night was one of the best of this series, being well attended and much interest shown in the subjects discussed. On the morning of August 3, I walked to Hatzic with Mr. Tom Wilson, a member of the Provincial Board of Horticulture, and examined several fine orchards, many of which, however, were seriously injured by the attacks of the Pear Slug, against the injuries of which no steps seemed to have been taken. From Hatzic we proceeded by steamer to Chilliwack, where a most successful meeeting took place. Chilliwack is one of the most favoured spots in British Columbia and the meetings, being always well worked up, are invariably satisfactory. On the afternoon of the 3rd we drove out to inspect a currant plantation belonging to Mr. Ford, which was heavily infested by a downy scale insect, *Pulvinaria occidentalis*, Ckll, the western representative form of the well-known eastern Cottony Maple Scale, *Pulvinaria innumerabilis*, Rathvon. Leaving Chilliwack on the morning of the 4th, we reached Agassiz before noon. The afternoon was spent in examining critically the pastures of the Experimental Farm with a view to discover if possible any plants which might be the cause of the disease among cattle known as 'Red Water.' Nothing of importance was discovered, and none of the plants reputed to be the causes of this obscure disease were found in undue abundance, nor could it be seen that any of those which did occur had been eaten by stock which had fed there. A very successful meeting of the Farmers' Institute was held in the evening. This was well attended and was followed by a protracted discussion. In addition to Mr. Anderson and the writer, Mr. Thomas Sharpe delivered an address.

Starting at 4 o'clock on the morning of August 5, an expedition was made to the summit of Mount Ché-am for the purpose of collecting botanical and entomological specimens. We were accompanied by Mr. Allan Brooks, an enthusiastic ornithologist, and one guide, Jim Harris, a Ché-am Indian from Popcum, well acquainted with the mountain and an experienced climber, who was of great service to us. Notwithstanding the lateness of the season and the exceedingly unpropitious state of the weather which prevailed while we were on the mountain, we made large and valuable collections

both of plants and insects. As a result of the late season, we found on the summit banks of snow 75 and 100 feet deep, where last year at the same date we had seen deep ravines. On the morning of August 8, it began to rain at 6 o'clock, so we decided to descend at once, and at eight o'clock struck camp and began the descent of the mountain in a downpour of rain, which continued all day till we got to the base at 16 o'clock, drenched to the skin, but with all of our specimens safe, as we had wrapped them in waterproof covers before starting. At Popcum we took a hasty meal and crossed the Fraser River by 17.30 o'clock. The following morning was fully taken up attending to our specimens and in drying our clothes to be ready to leave for the upper country on the train at 15.47 o'clock.

We reached Sicamous on Shuswap Lake at 2.35 o'clock and waited there in pouring rain till 6 o'clock, when we took the Okanagan Valley train for Armstrong, arriving there at 9 o'clock. We had hoped to have collected many specimens in this locality, but it rained all day. Our time, however, was by no means wasted, for we examined a very interesting local collection of plants and insects made by Mrs. Walton, of Armstrong, and in the evening held one of the best meetings of our whole trip. This was of the Spallumcheen Farmers' Institute. Some of the worst weeds of the Northwest, including the Tumbling Mustard, False Flax and Ball Mustard, were found to have gained a foothold in this fertile valley, and the farmers were keenly interested in learning all that was to be known about them. The Prickly Lettuce (*Lactuca Scariola*, L.) and the Purslane (*Portulaca oleracea*, L.), both of gigantic dimensions worthy of the Pacific Province, were brought to the meeting. We left Armstrong at 9 o'clock on the morning of August 11, for Okanagan Landing, where we took the fine steamer *Aberdeen* for Kelowna, and reached there at 16 o'clock. After being shown over the new and up-to-date factory of the Kelowna Shipper's Union, where the now well known 'Flor de Kelowna' cigars are made, we were driven out to see the surrounding country by Mr. J. T. Davies, the President of the Okanagan Farmers' Institute. We first visited Lord Aberdeen's ranche at Guisachan, where we were shown fields of Smooth Brome grass. We then visited the extensive and successful tobacco plantations of Messrs. Collins and Holman, and finally accompanied Mr. Davies to his own home. The meeting at Kelowna was held at 20 o'clock in the evening and was, as is always the case at this bright active little town, well attended and very successful. We left this delightful place at noon on August 12 and reached Enderby at 18 o'clock the same evening ; there we left the train and drove across the country to Salmon Arm, arriving at 20.30 o'clock, just in time for the meeting of the Salmon Arm Farmers' Institute. This meeting, although not so largely attended as those at Armstrong and Kelowna, was full of interest, as this place is becoming a fruit growing centre of importance in the province. The addresses were attentively listened to and fully discussed.

This was the last of a series of sixteen useful and most enjoyable meetings held with Mr. Anderson in the best agricultural and fruit growing districts of British Columbia. Mr. Anderson's thorough knowledge, not only of the capabilities of his province, but also of its fauna and natural history, made him a most entertaining companion ; the careful arrangements he had made beforehand enabled me to take the fullest advantage of the expedition, which was of inestimable value to me in becoming acquainted with the conditions prevailing in the various localties visited, so that I might be of as much use as possible in the future to such farmers of British Columbia as may wish to correspond with the Division of Entomology and Botany.

We left Salmon Arm at 1.25 o'clock and reached Banff, Alta., by 17 o'clock on August 13. I remained there until the next day, when in company with Mr. W. C. McCalla of St. Catherine's and Mr. N. B. Sanson, Curator of the Government Museum at Banff, both enthusiastic botanists we sallied out, and, notwithstanding the torrents of rain which fell almost continuously, I added several desirable botanical specimens to my collections. On August 14, I left for home at 16.10 o'clock, reaching Winnipeg at 21 o'clock on the 15th, and Ottawa at 18 o'clock on August 17.

REPORT OF THE POULTRY MANAGER

(A. G. GILBERT.)

To Dr. WM. SAUNDERS,
Director Dominion Experimental Farms,
Ottawa.

SIR,—I have pleasure in herewith inclosing to you the twelfth annual report of the Poultry Department.

The work of the year embraced certain experiments, particulars of which are given in full under their distinguishing headings. Briefly outlined they are :—

Experiment in order to ascertain the laying qualities of old hens and pullets.

The placing of three groups, of five each, of Barred and White Plymouth Rocks and Silver Laced Cockerels in pens with limited runs attached, with the object of finding the relative value as flesh formers of rations composed of whole grains, another of ground grains and a third embracing both.

Penning up cross-bred cockerels and feeding them on ordinary rations with the view of noting flesh development.

The preservation of eggs, in order to find out the best means of doing so.

Artifical incubation.

An important feature of the year was the discovery of a fatal disease among turkeys, new in Canada but not in the United States. The disease Entero-Hepatitis has no doubt been the cause of the death of many turkeys throughout the country. A description of the disease and manner of its discovery will be found in its proper place.

Addresses on subjects kindred to my department were delivered during the year at different points in the country.

The increase in volume of correspondence and demand for literature on poultry keeping, as well as the erection of numerous houses by farmers and poultry plants by private individuals and joint stock companies, denote rapid development in poultry culture for profit.

It affords me pleasure to again testify to the zeal and energy of Mr. George Deavey, to whose proper handling of the rations, so much success in the production of eggs in winter and the rapid growth of the chickens in summer is due.

I have the honour to be, sir,
Your obedient servant,

A. G. GILBERT.

CENTRAL EXPERIMENTAL FARM,
OTTAWA, December 30, 1899.

The work of the past year differed from that of the previous years in so far that during the period of winter laying, which is one of the most important, the laying stock were divided into three sections, viz. :—

1. Old hens of three years of age and over.
2. Hens twelve months of age, known as yearling hens.
3. Pullets, always understood to be of that season's hatching.

The divisions were made for the purpose of experimental investigation into the laying merits of the hens of the different ages designated.

There has always been much speculation, but no satisfactory data, as to the egg-producing value of the older and younger stock. Each class had its votaries. There were those who contended that pullets were the best money makers, because they laid the most eggs. Again, there was the statement that while pullets might lay more eggs than the older hens, their eggs were not worth so much, because smaller in size. And a third party, whose contention is that the eggs of the two-year old hens were best to hatch chickens from, because the progeny were more likely to be strong and robust than offspring from eggs of pullets, which are immature fowls.

The claims of each party certainly embraced strong features and afforded scope for interesting investigation.

Accordingly, the fowls, on going into winter quarters during December of last year, were divided into three groups as described above.

Many of the old hens were three years of age, and some over that figure, so that good opportunity was afforded to make fair comparison.

The following table will show the results of the experiment, it being borne in mind that the object was to have eggs in winter, the season of high prices :—

TABLE showing comparative laying merits of Old Hens, Yearling Hens and Pullets.

Number.	Description.	December.	January.	February.	March.	April.	May.	June.	Total.	
	OLD HENS.									
13	White Leghorns..........	40	50	32	91	130	160	88	591

8	Black Minorcas.....	25	39	102	77	91	94	24	452	" May 9 and May 26.
8	Brown Leghorns..........	18	81	77	104	87	114	47	528	" May 17.
48									3,174	

The fowls were kept under the same conditions, with the exception of food, of which the pullets received a greater quantity for reasons given further on.

Some of the points shown by the table, are :—

1. The pullets laid more eggs than either old or yearling hens, except in the case of seven old Black Minorca hens.

2. The eggs of the older hens were larger and in consequence worth more. Mr. Walter Paul, family grocer, of St. Catherine Street, Montreal, says in a letter, 'we pay more for the new laid eggs of large size.'

3. The laying of more eggs by seven Black Minorca old hens, than by eight pullets of the same breed, goes to show that the contention that the hens of the Mediterranean classes are good layers up to three years of age inclusive, is warranted in this case.

4. If eggs were sold by weight, the larger eggs of the older hens would be most in demand.

5. The late May and middle of June hatched Langshan pullets, did not lay half as many eggs as the same number of earlier hatched Barred Plymouth Rock pullets. There can be but one deduction and that is to have the pullets of the Asiatic and American breeds hatched as early as possible.

WEIGHT OF HENS AND PULLETS EGGS.

The weight of eggs of different breeds is given as follows :—

HOW TO HAVE EARLY HATCHED PULLETS.

Early hatched pullets may be secured in two ways, viz.:—

1. By using hens to hatch them.
2. By incubators and brooders, or brooding house.

The first method is more likely to be practised by the great majority of farmers, for the time being at any rate. But there are certain conditions in connection with hen-hatched chickens that the farmers must be acquainted with or desired results cannot be obtained. It must be borne in mind that in order to have early sitters, the hens of the sitting breeds should lay in winter. If they do not, as is too frequently the case, they will not become broody until they have laid their quota of eggs in spring, and this, with the further period of three weeks required for the hatching of the young birds, may mean the end of May or the beginning of June before the first chickens make their appearance. Past experience in our poultry department has shown that when Plymouth Rocks, Wyandotte or other hens of the sitting varieties lay, all winter, there are broody hens enough in March or early April to hatch out many chickens by first week in May ; and early May chickens, with proper care and food, have been found to grow rapidly. The weather is always a factor. Some seasons are milder and earlier than others. Early May hatched pullets, of the American breeds, should lay in late October, or early in November. In 1897, one of three Barred Plymouth Rock pullets hatched in our poultry department on March 11, laid her first eggs on September 20 following, (five months and nine days), and the others shortly afterwards. A year or two previous a Barred Plymouth Rock pullet hatched April 29, laid her first egg four months and

twenty-nine days later. She was the earliest pullet to lay in the history of the department. Early May hen hatched chickens, seem to grow best and give the most satisfactory results as flesh formers and layers. Earlier in the season the weather is too cold to permit a rapid growth, unless mother and brood are placed in a warm compartment, and the floor covered with earth. Or when the chicks have been taken away from the mother hen and placed in a properly constructed brooder, or brooding house. In the colder portions of the Dominion where ordinary facilities are at the disposal of the farmers, hen-hatched chickens of early May will be found to give the best satisfaction.

THE SECOND METHOD OF RAISING EARLY PULLETS.

But it may be said—indeed is often said by correspondents—that pullets are wanted to lay four or six weeks earlier than those which are hen hatched, or at the time when the older hens are in moult and eggs scarce and high in price. In such a case recourse must be had to the second method, viz.:—

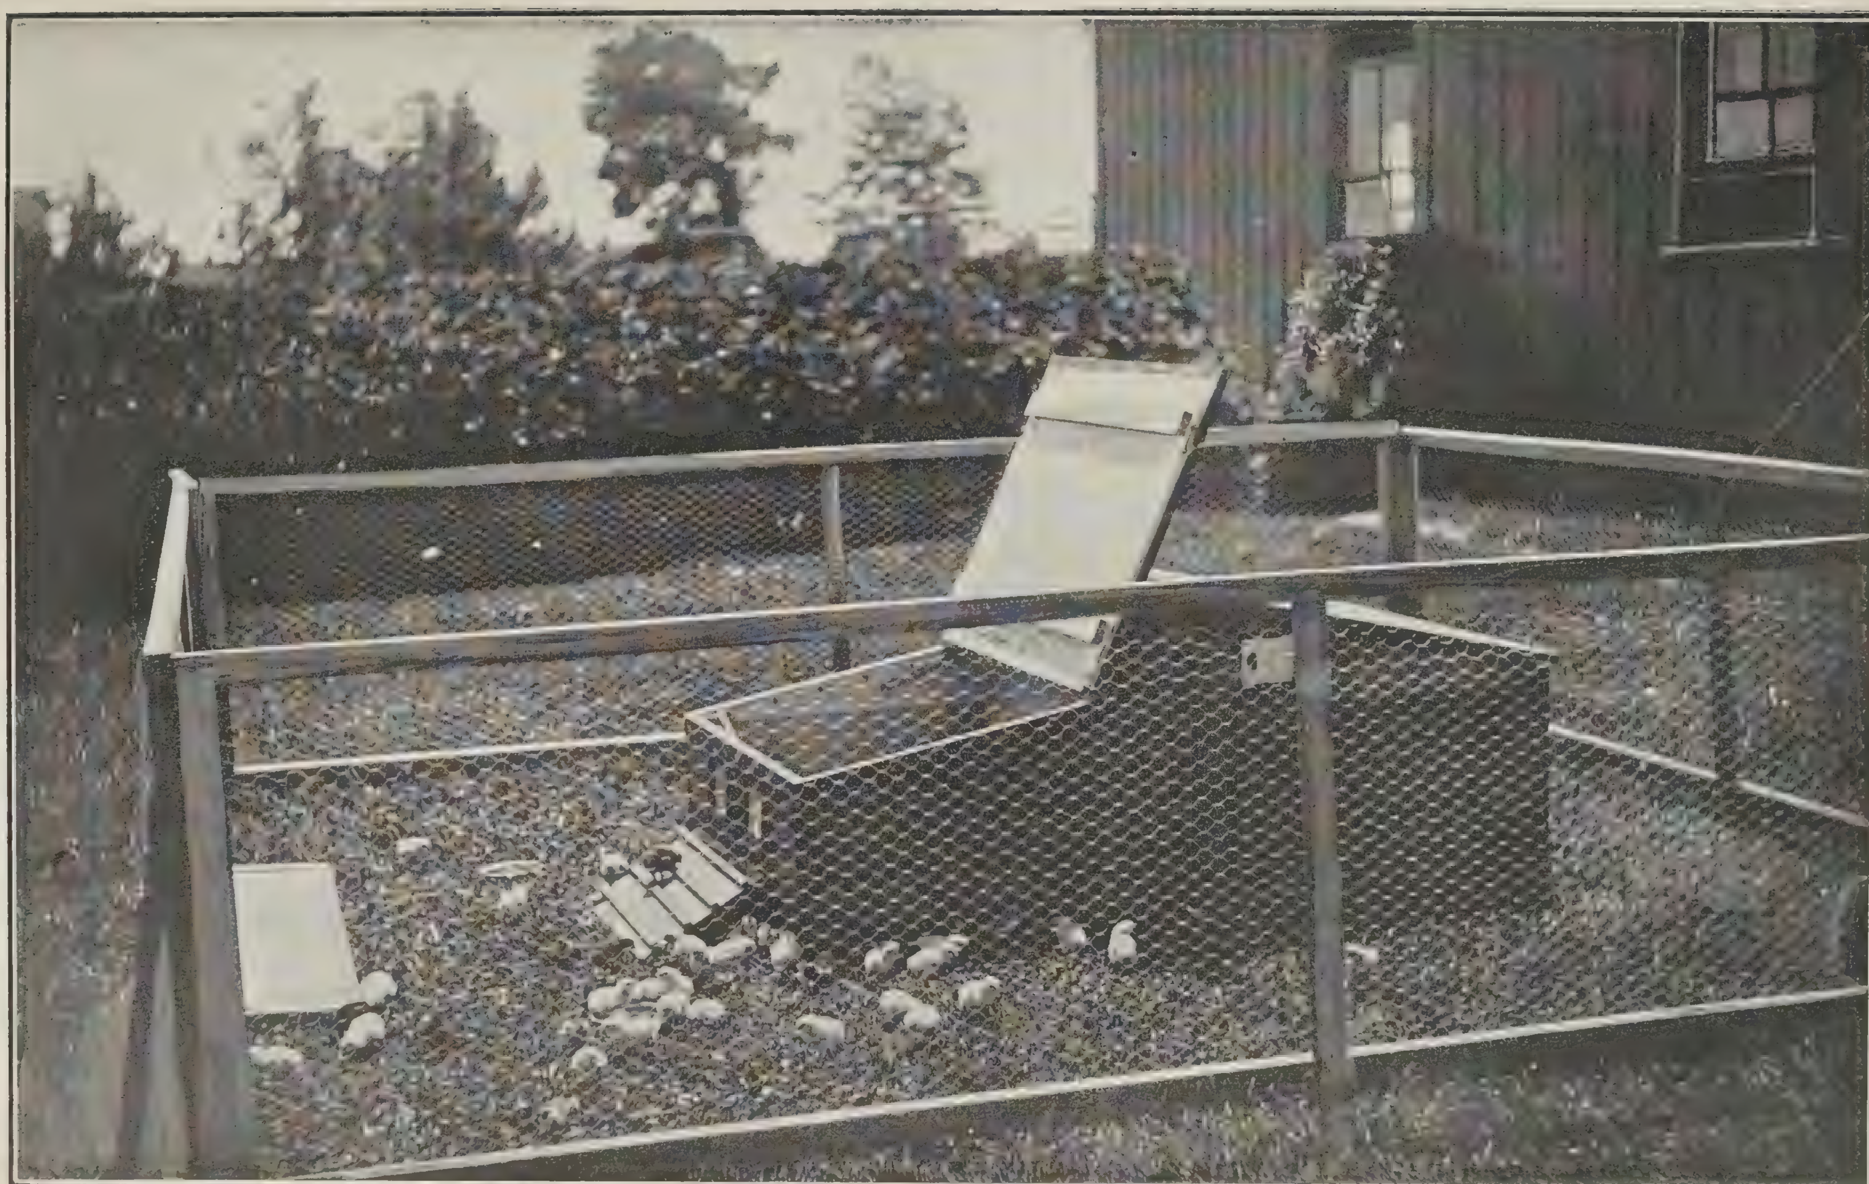
By incubators and brooders, or brooding houses. The early hatching and rearing of chickens by artificial means is becoming more in vogue because incubators and brooders have become more easy in operation and certain in results. It is certainly the only way by which one party, or a company of capitalists can hatch out a large number of chickens during the winter months or early in spring. If only a limited number of eggs are required for incubator use in late winter or early spring and the hens are also stimulated to lay eggs for sale in December and January and part of February, skill and experience are required in the handling of the laying stock, so as have a large percentage of the early eggs fertilized. In certain cases it may be advisable to keep a number of hens to lay eggs for incubator use only. Where chickens are wanted in comparatively small numbers a good brooder, or sectional brooder house, may be found sufficient, wherein to care for the chicks, until the weather permits of their being put in coops outside. But in large establishments where the artificial hatching and rearing of chicks for sale as early broilers is conducted on a large scale, an extensive brooding house is required. In such establishments a great number of hens are kept mated and managed so as to lay as large a percentage of fertile eggs as possible. Hatching by incubators begins in December or early January and the chickens do not leave the brooding house until put on the market, ten or twelve weeks later. Few eggs are sold for eating purposes, the aim of the management being to convert the dozen eggs, which for eating purposes are worth at city prices 35 or 40 cents, into broilers or early roasters worth at the proper season $1.25 to $1.50 per pair. A dozen eggs from which are hatched six or eight chickens, after making allowance for cost of rearing, affords at the figures mentioned a large margin of profit to the skilled and experienced managers. Speaking on the subject, Mr. A. F. Hunter, the well known proprietor of Cleft Rock Poultry Farm, South Natick, Mass., said 'while some persons are content to so manage their hens as to make only 40 cents per dozen on the city markets for their winter eggs, others by their skill in management and expert knowledge of artificial incubation make the dozen eggs worth to them four to five dollars. The margin of profit is there. It is only a matter of skill and perseverance to make it.'

There are several farmers in Canada who successfully use incubators and who are on the way to be specialists. They are found in the neighbourhood of the larger towns and cities. But the great majority of our farmers have yet to learn how to have their hens lay in winter and their energies meanwhile should be directed to

1. So managing their hens as to have eggs in winter.
2. And so have, not only a high price for their eggs, but early sitters to hatch out early chicks for market and pullets for early layers.

HOW THE OLDER HENS WERE FED.

Previous experience had shown that the same quantity of food given to the pullets with good results when fed to older hens made them too fat. Accordingly the older



Brooder in inclosure in Poultry Department, Ottawa, with Chickens Hatched with Incubator.

hens were fed rations, in such quantities, as past experimental work had shown was best for egg results and health of stock, viz :—

MASH, composed of ground grains, with ground clover, or vegetables mixed into it, in proportion of one quart to every fifteen hens. Fed three times per week, in morning and sometimes in afternoon.

CUT GREEN BONE, one pound to every fifteen or sixteen hens three times per week, or, at such times as the mash was not given.

WHOLE GRAIN, principally wheat. Fed for afternoon last ration, in quantity about 5 to 7 pounds to every 100 hens.

After morning ration, oats, sometimes millet seed, in small quantity were scattered in the litter on the floor of the pens to incite to exercise.

At 11 a.m. lawn clippings steamed were given. Vegetables, principally mangels, were before the layers all the time. Mica grit, crushed oyster shells and pure water were in constant supply. While cabbages were to be had they formed part of the green food.

HOW THE PULLETS WERE FED.

The pullets were fed more than the older hens. A little mash and a small quantity of cut bone were fed every day, but at different times.

Whole grain composed the afternoon ration.

The feeding of mash, cut green bone and whole grain actually represented three rations per diem.

As with the older hens, steamed lawn clippings, vegetables and the other essentials mentioned were regularly furnished.

Careful watch was kept on the birds in order to detect the slightest effect of this stimulating ration on their condition. At the end of January the Barred Plymouth Rock pullets showed symptoms of being overfat. Accordingly the rations of all the pullets were reduced to the same number and quantity as fed to the other hens. Meanwhile the output of eggs was most satisfactory, as the following table will show. It will be noticed that on several days, during mid-winter, that six eggs were obtained from a pen of eight pullets and more frequently five and four eggs, which is remarkably good laying. Particulars will be learned from the following :—

STATEMENT showing eggs laid per day by Pullets during December, January, February and March.

EXPERIMENT 2.—FATTENING OF PLYMOUTH ROCK AND WYANDOTTE COCKERELS ON WHOLE AND GROUND GRAIN, THE BIRDS HAVING LIMITED RUN.

On the 15th of August, 1899, three groups of five birds, in each group, of thoroughbred Barred and White Plymouth Rocks, and Silver Laced Wyandottes, were placed in separate pens with limited outside run. The birds wore legbands with distinguishing numbers.

Each group was fed on rations of different sorts.

No. 1 Group of five Barred Plymouth Rocks was fed solely three times per day, on whole grain consisting of two parts of wheat, one part barley, one part corn.

No. 2 Group of five White Plymouth Rock Cockerels were fed three rations per diem, on grains of same kind and in same proportions as fed to No. 1 group, but ground and mixed into mash.

No. 3 Group.—Five Silver Laced Wyandottes were fed the rations usually given to the growing chickens, viz., mash twice and whole grain once per day.

The amount of food given to each group of five birds per day was 12 oz., or 4 oz. three times per day, viz., morning, noon and afternoon. The value of the ¾ lb. ration per day was placed at 1 cent per day per group of five birds, or 3 cents per day for three groups of fifteen birds.

It had been observed after feeding several rations that no more food was consumed than the quantities named. It was consequently resolved not to increase the amount but to note the effect of these apparently limited quantities. The cost of food per day of 1 cent for the five birds is corroborated by the experiment with fifty hens, particulars of which are given in 1897 report, and in which it is shown that fifty hens were kept in winter at 10 cents per day and gave satisfactory results in eggs.

The following statement shows the weight development per bird per week :—

TABLE showing gain made by three groups of thoroughbred cockerels fed on whole grain, ground grain and a mixed ration respectively.

* At the end of the tenth week the birds were allowed an unlimited run in a large field, and made in the majority of cases better progress than they did in the limited run.

EXPERIMENT 3—PROGRESS IN WEIGHT DEVELOPMENT MADE BY CROSS-BRED COCKERELS ON ORDINARY RATIONS.

On November 7 last, twelve cross-bred cockerels, as described further on, were put into small coops, each coop containing a single bird. The coops had a feeding trough in front of them, and were the same as used in the fattening of thoroughbreds experiment of the previous year.

The birds were fed on the ordinary mash giving to the laying stock.

The object of the experiment was to ascertain the weight development of these first crosses without any specially prepared food or special effort beyond cooping them up and feeding them three times per day.

The following are the crosses composing the dozen birds :—

Nos. 1 to 9—Cockerels of White P. Rock-white Leghorn cross.
No. 10—Cockerels of Light Brahma, P. Rock "
No. 11—Cockerels of White Wyandotte-Brahma "
No. 12—Cockerels of Andalusian "

The gain per week made by each bird is shown in the following table :—

Flesh Development of 12 Cross-bred Cockerels on Ordinary Rations.

12	Andalusian Cockerel "	4	2¼	4	1¾	4	10½	4	14¾	4	15¾	..	13½	"

The progress made both before and after being put in fattening coop was very satisfactory. The highest weight development was made by Nos. 4, 7 and 9 of the Plymouth Rock-Leghorn first crosses. At end of 5 months and seven days these birds showed weight respectively of 5 lbs. 5½ oz. ; 5 lbs. 4¾ oz. and 5 lbs. 5 oz., or a weight per pair of 10 lbs. 10¼ oz. A weight much greater than that of the ordinary market fowls.

The weight development of the Light Brahma-Plymouth Rock cross of 6 lbs. 6¾ oz. in six months and 5 days, is also satisfactory, and goes to show that with equal care and feeding the incubator hatched and brooder reared chickens do as well as the chicks hatched by hens.

But the experience of past years leads to the conclusion that while certain first crosses may do nearly as well as thoroughbred Plymouth Rocks, that it is better for farmers to make choice of thoroughbred fowls, in the first place, and keep no other kind. A first cross would necessitate the keeping of two breeds and unless made every year would quickly degenerate into nondescripts.

FARMERS AND THOROUGHBREDS.

Some time ago Mr. A. McPhadden, a farmer of Dominionville, Ont., was advised, in reply to a letter from him, to pen up a certain number of Barred Plymouth Rock cockerels and feed them on ground grains.

He did so, and recently wrote: 'I started two weeks ago (October 25) to fatten eight B. P. R. cockerels, as advised by you. I had not a suitable place, so I put them in crates. I fed the first week as directed, three parts oatmeal and one of pease. The second week cornmeal was added. The third week the cornmeal was increased. The result was:

Total gain first week, 7 lbs. or $\frac{7}{8}$ lb. per chick.
" second week, 4 lbs. or $\frac{1}{2}$ lb. per chick.
" third week, $2\frac{2}{3}$ lbs. or $\frac{1}{3}$ lb. per chick.

The cost of producing 1 lb. of flesh was $5\frac{2}{5}$ cents per lb. I am satisfied with my experience in fattening thoroughbreds, and would not keep any other fowls now but thoroughbred Barred Plymouth Rocks.'

Subsequently Mr. McPhadden sent a number of his fattened chickens for sale to certain customers in the city. The weights of some of the cockerels were as follows:—6 lbs. $14\frac{3}{4}$ oz.; 6 $5\frac{1}{4}$; 6 $2\frac{3}{4}$; 6 $13\frac{1}{2}$; 6 $11\frac{1}{2}$; 5 14; 5 $13\frac{1}{4}$; 5 9. The birds sold at 10 cents per lb., plucked, but not drawn. They were certainly of a very superior quality.

Another well known farmer in the neighbourhood of Guelph, Ont., Mr. Laidlaw writes under date of October 17: 'I have raised a large number of barred and buff Plymouth Rocks and Silver Laced Wyandottes. They weigh at present without any special fattening $4\frac{1}{2}$, $5\frac{1}{2}$, 7 and 8 lbs. each, the latter being a few early ones.'

On October 28, Mr. Laidlaw wrote to say that 'the average weight of all my Plymouth Rock and Wyandotte cockerels was $5\frac{1}{2}$ lbs. each. Had they been penned up and specially fattened doubtless they would have weighed more. I have sold all my chickens to a buyer for shipment to the west, at much better profit than I could have made on the local market. Next season, all being well, I will get the names of the Montreal poultry dealers from you.'

It is satisfactory to note, in the latter case, to what weight the thoroughbred chickens attained, because cared for and fed properly from time of hatching. Before the first named farmer, Mr. McPhadden, had put his Plymouth Rock chickens into the fattening crates, they had made rapid flesh development, because they had also been carefully looked after and fed from time of hatching. It is well for the farmers of the country to bear in mind what has been said in previous reports, that a chicken neglected in the first five weeks of its existence seldom or never makes a satisfactory market chicken, or early layer.

The experiences of Messrs. McPhadden and Laidlaw are given to encourage those who have begun to breed the superior quality of poultry flesh, and to incite those who have not yet done so to make a beginning.

BREEDING PENS MADE UP.

On the 3rd of January the following breeding pens were made up:—

Breeds.	Cocks.	Cockerels.	Hens.	Pullets.
Coloured Dorkings	1	....	6	....
Langshans	1	....	....	12
Light Brahmas	1	....	4	3
Andalusians	1	....	7	3
Brown Leghorns	1	....	....	12
On March 1, following were mated up for producing crosses:—				
Leghorn Hens ....3, Coloured Dorking Hens 2 } B.P.R. Cockerel	....	....	....	....
On March 21, were mated Silver Laced Wyandottes	....	1	7	....

Male birds were with the Barred Rock, White Leghorn and Black Minorca hens all winter.

In several instances the early spring eggs were not as fertile as could have been desired. This may have been due to any of the following causes :—

Eggs from hens which had laid all winter.

Eggs from hens which had become overfat.

The effect of the long period of artifical life and treatment, in limited quarters, on the layers.

The subject has been already discussed at length in a previous chapter on how to secure early pullets. It is one of great importance, and is being made a matter of experimental investigation. Much seemingly depends upon any or all of the following :—

1. Kind, vitality and age of the laying stock.
2. Construction of building and temperature of same.
3. Composition of rations and quantities in which which they fed.
4. Condition of male and female breeding stock at time of mating.

DEMAND FOR EGGS FOR HATCHING NOT SO GREAT.

Eggs for hatching purposes were not in such demand last spring as in former years. This may have been partly owing to the greater number of farmers who sold eggs from their thoroughbred stock to other farmers. And it is a matter of congratulation that such is becoming the practice. The farmers of the country cannot over-estimate the value of thoroughbred stock to them for egg laying or flesh forming, as compared with the nondescript that is seldom good for either.

The following are the results from the eggs set under hens at the dates given. In some instances poor hatching was due to erratic and clumsy sitters, or to thin shells of the early eggs. In two instances eggs coming from a distance showed rough handling en route. In most instances the eggs were tested on the sixth or seventh day of incubation and their condition at the time is noted.

HOW THE CHICKENS WERE FED.

The chickens made rapid and satisfactory progress on the following food and treatment:—

First food after coming from nest, where they remained for twenty-four hours after hatching: stale bread crumbs; stale bread soaked in milk and squeezed dry.

Second day. Stale bread soaked in milk. Granulated oatmeal. Milk or water for drink.

The same for three or four days longer, when finely crushed corn was given in moderate quantities.

At the end of ten or twelve days, mash composed of shorts, cornmeal, stale bread waste, broken crackers, boiled potatoes, was given two or three times in lieu of the bread and milk.

At end of fourteen days wheat was added to the bill of fare. It was fed in small quantities at first, principally at last ration for the day.

As the chickens grew their food was made as cheaply and wholesome as possible. The waste of table and kitchen may be put to good use in this way.

The chickens were fed a little food at a time, but frequently. Care was taken to avoid overfeeding in the earlier stages of life. It is better to feed only what the chickens can pick up cleanly at a meal, rather than to leave a quantity of food to turn sour and become filthy.

When sufficiently old to run about and obtain insect life the rations were reduced to three per day.

On the above rations the farmers will find their chickens grow vigorously. It is well to remember that any extra care and attention during the earlier stages of chicken life is well repaid afterwards in early maturity and increased weight.

The tables in connection with experiments 2 and 3 to be found on preceding pages will show the weight development made by cockerels of the heavier breeds and some crosses.

WHEN THE PULLETS BEGAN TO LAY.

The pullets commenced to lay in the following order:—

Brown Leghorn pullet	hatched	June 10,	laid first egg	November 15.
White Minorca	"	May 22,	"	December 10.
B. P. Rock	"	" 26,	"	" 12.
Langshan	"	" 22,	"	" 15.
Black Minorca	"	June 21,	"	" 15.
W. Wyandotte	"	May 27,	"	" 25.

THE MOULTING SEASON.

As in previous years every effort was made to get the hens through their moult as early and as quickly as possible. In order to accomplish this the cock birds were removed from the breeding pens during the first week in July and placed in small pens, in another building, with outside runs attached. The hens were then allowed to run in small fields (in rear of the poultry buildings) where they found grass, clover and insect life. They were so allowed to run until middle of August when they were given, three times per week, a mash composed of ground grains with a small quantity of linseed meal. By the middle of October the majority of the laying stock were in new feather.

WHEN WINTER LAYING COMMENCED.

The stock went into winter quarters in good health and condition. The season was unusually open, permitting the fowls to have outside run until the second week in December. Winter laying commenced about the 12th day of December. The first hens to lay were Brown Leghorns, Minorcas and Plymouth Rocks. The greatest number of eggs during the latter half of December, were laid by Brown Leghorn hens,

and Brown and White Leghorn pullets. The following shows the daily output of eggs by the number and description of hens given :—

9 BROWN LEGHORN PULLETS.

From December 11 to 31, inclusive :—5, 2, 3, 3, 3, 2, 5, 2, 4, 4, 3, 4, 4, 3, 4, 5, 3, 4, 4, 3, 3.—73.

8 WHITE LEGHORN PULLETS.

From December 10 to 31, inclusive :—3, 1, 1, 1, 3, 1, 1, 4, 2, 2, 3, 2, 2, 4, 3, 3, 3, 2, 5, 3, 4, 3.—56.

10 BROWN LEGHORN HENS.

From December 11 to 31, inclusive :—1, 1, 1, 2, 5, 2, 6, 4, 4, 4, 3, 5, 3, 5, 2, 5, 2, 4, 2, 2, 2.—65.

EGGS LAID DURING PAST YEAR.

The stock on hand at beginning of last season was 125 hens and 80 pullets. Among the hens were 50 or 60 old ones, which were kept over for sitters and breeding stock and also to take part in the laying test of old hens *vs.* pullets, particulars of which will be found in a preceding page :—

STOCK ON HAND.

During late summer the great majority of the two and three year old hens were disposed of. As they were of superior quality they will make excellent breeding stock for a year or two more. The following is the number of stock on hand on the 11th of December, 1899 :—

Breed.	Hens.	Pullets.	Cocks.	Cockerels.

RATIONS OF PRESENT WINTER AND HOW FED.

The following are the rations of the present winter and the quantities in which they are fed :—

TO 100 HENS, ONE YEAR OLD.

Six and one-half lbs. ground grain made into mash with boiling water. The proportions are two parts shorts ; one part ground oats, barley or rye ; one part cornmeal. Varied by having clover meal or boiled roots mixed into it. Fed morning or evening three times per week.

Cut Green Bone.—Three times per week in proportion of 1 lb. to fifteen hens. Fed morning or evening when mash is not given.

Afternoon Ration.—5 to 7 lbs. of whole wheat, as may seem necessary, and when mash or cut bone is not fed.

No noon ration is given. Mangels or other roots are before the hens all the time. If they desire more food they can find it in the roots.

Mica grit, ground oyster shells and water were in regular supply.

When mash or cut ground bone is fed in the morning, a few handsfull of oats or a handfull of millet seed are scattered in the litter on the floor to incite the hens to exercise.

At 11 a. m. on days when clover meal is not mixed in the mash, steamed lawn clippings are given in limited quantity.

NINETY-NINE PULLETS.

The same rations as above and in same quantities are given to the pullets. For the reason that last winter a little mash and a small quantity of cut bone were given to the pullets every day, but was found too fattening and stimulating. This season the rations as described above are being tried. So far results have been satisfactory, as will be seen in a preceding page, which shows the number of eggs laid in latter half of December by nine brown Leghorn pullets, ten hens of the same variety, and eight white Leghorn pullets.

DISEASES OF POULTRY.

During the past year numerous letters were received describing the symptoms of different ailments, and asking for remedies. In most cases the sickness could be traced to overfeeding—especially in the case of old hens—and consequent fatal liver disease. In other cases the symptoms pointed to colds or roup, the latter frequently following the former. Ill ventilated and overcrowded quarters were also sources of ailment.

A FATAL TURKEY DISEASE.

Many letters had been received describing the symptoms of a disease which had been fatal to many turkeys in Ontario and the Eastern Townships. About the first of November last the following inquiry by a subscriber was received from the editor of *Farming*, Toronto, with the request for an immediate answer for publication :—

To THE EDITOR OF FARMING.—Will you inquire for me through your paper how to treat sick turkeys. My turkeys are drooping. Their droppings are of a green and yellow colour at the time of their sickness, and they do not last long when they take sick.

FARMER'S DAUGHTER.

A reply was made to the effect that the symptoms pointed to liver disease, or acute dysentery, caused by eating improper substances, perhaps in the shape of decayed animal or vegetable matter, and recommending the use, in the soft food, of a good condition powder and the dropping of a small piece of alum into the drink water. The suggestion was also made that the farmer's daughter should send a turkey, which had just died, to the Bacteriologist, Ontario Agricultural College, to ascertain whether death was due to germ disease or not.

THE DISEASE LOCATED.

The farmer's daughter kindly complied with my request, and the result of her disinterested action was the discovery of a disease presumably new in Canada, and which probably, heretofore, has been the cause of death of many thousands of turkeys throughout the country.

The following letter from the bacteriologist at the Guelph Agricultural College will explain the nature of the disease :—

O. A. C., GUELPH, November 23, 1899.

DEAR MR. GILBERT.—I have this day examined a turkey received from some one in Fergus, who does not give any name. It is a case of Entero Hepatitis—described in a Washington publication entitled 'Infectious Diseases of Poultry.' This is, so far as I know, a new disease in Canada, the only account of similar cases being in the publication already mentioned. I believe it has also broken out at another farm in this neighbourhood, because I am told there are turkeys dying there with spots on their liver. I thank you for giving us an opportunity of examining the disease. I may say that my roup investigations are going on, and that I believe roup is caused by a somewhat similar organism as is the turkey disease. I shall always be pleased to examine birds.

Yours sincerely,

MALCOLM ROSS.

DESCRIPTION OF THE DISEASE.

The following extract from the full and elaborate description given by Dr. D. E. Salmon, chief of the bureau of animal industry, Washington, U.S., in the publication referred to by Prof. Ross, will be found interesting :—

'The external appearance of the turkeys affected with the disease do not seem to be constant, and this is not to be wondered at in view of the varying intensity of the changes found in the internal organs. In Rhode Island the disease is known as 'blackhead' owing to certain peculiar discolorations which take place at the height of the disease. While it might be well to retain this as a popular name we do not believe that all cases of blackhead have the specific disease herein described, nor do all turkeys affected with this disease manifest the appearances of blackhead. Among the symptoms which may be expected to appear sooner or later, diarrhœa occupies a prominent place. The disease of the cœca is responsible for this. * * * Emaciation was not constantly present in the cases dissected by me. The disease seems to attack turkeys when quite young. It seems moreover as if the disease were contracted only by the young, because in the examination of turkeys of different ages the oldest showed lesions of the oldest standing. * * * The most serious and extensive destruction of tissue was noticed in the turkeys in fall. In midsummer the disease was making most progress, that is, it was freshest and the microparasites present in great numbers. It is probable that the delicate tissues of the young are best adapted for the temporary habitat and rapid multiplication of this parasite. The primary seat of the disease are the cœca. From these the liver is invaded. Other organs are not attacked. * * The appearance of the liver in the average case of this disease is very striking * * * Twice the normal size is probably near the truth. * * * In the case of No. 2 the liver weighed 10·7 ounces. * * * The processes

of advancing disease and necrosis on death of tissue on the one hand, of repair on the other, seem to go on side by side, now one now the other, predominating. * * The blood of many of the cases was examined before the bird was killed, in order to to detect any existing blood infection. No disease of the blood was observed except in the case of No. 16. * * *

The results of the examination of turkeys made thus far indicate that the disease may follow several courses.

(1.) After a certain period of disease regenerative processes begin which tend toward a permament recovery.

(2.) The disease may proceed so rapidly from the very start that the affected turkeys die early in life.

(3.) The disease may come to a standstill, but the amount of dead tissue in the cœca and liver may be so great as to favour the entrance of bacteria which are responsible for the death of the bird late in the summer or fall.

As regards the spontaneous cure of infected birds, we may regard it as probable that only those in which the disease comes to a standstill before it has made much headway are likely to recover. In those in which much destruction of tissue has taken place complete recovery is impossible. * * *

SOME CONCLUSIONS.

Investigation so far leads to the conclusion that infection takes place early in life.

That the microparasite, discharged perhaps in an encysted stage from the sick bird, is taken up with the food and water by others and sets up disease directly.

By uninterrupted transmission the disease becomes perpetuated and diffused among neighbouring flocks.

If the theory that the disease is transmitted more or less directly from old to young should prove to be true, the remedy for such a state of affairs would appear to lie in two directions :

(1.) The disease might be allowed to go on and some remedy found which will check it and lead to a cure, or

(2.) The diseased flocks might be entirely destroyed and new birds obtained elsewhere, after a thorough cleansing and disinfection of the territory formerly occupied by the flocks.

TREATMENT.

All turkeys that droop, are unable to keep up with the movements of the flock, and even have diarrhœa may not be affected by the disease. Among 50 turkeys killed as suspicious cases none were found to have the protozoan disease. They were suffering from a variety of other affections, the causes of which, mentioned in their order of frequency were, lice, tapeworms, gapeworms, ticks, injury, and a diphtheritic disease of the cœca, not to be mistaken for the genuine protozoan disease.

The success which quinine has had in combating malaria leads to the suggestion of its use.

Disinfection of coops and other structures which have sheltered the birds and other poultry, is recommended to be carried on as for bacterial disease.

The following disinfectants are given as strong enough to kill spores of bacteria and likely to destroy the various stages of the protozoa :

1. Corrosive sublimate, 1 oz. in about 8 gallons of water. The water should be put into wooden tubs or barrels and the powered sublimate added to it. The whole should stand for 24 hours so as to permit of sublimate being entirely dissolved. Apply with spray pump, broom or mop. All dirt and manure should be removed before spraying. Being very poisonous the solution should be carefully handled and well guarded. The manure should be covered with lime.

2. Chloride of lime, 5 oz. to 1 gallon of water. To be applied in the same way.

3. Ordinary slaked lime is very useful and should be used more particularly on infected soil.

TROUBLE FROM LICE.

Lice infested fowls and poultry houses are the sources of annoyance and loss to many farmers and poultry keepers throughout the country. The following is a case in point. A few weeks ago a farmer of Kings, N.S., wrote that for two years past his hen house has been infested with a white louse or spider which it seems impossible to exterminate. The insect is very minute and is found in great numbers in every part of the house. They seem to hurt the hens, which do not lay, look pale in their combs and are light in weight. Death has occurred in some cases." A reply was made that the trouble was doubtless red mites, which when they make lodgment, swarm in cracks and crevices of the wood work of roost, platform and walls of the house. They do their work at night when they get, in great numbers, on to the flesh of the fowls and suck their life blood. Hens are weakened, become emaciated and do not lay. In some instances death follows. The remedy advised was to place the fowls in temporary quarters and then to remove all portable wood-work, old nests and contents, roost, &c., and to burn them. Then make up the following solution :

Corrosive sublimate	4 oz.
Common Salt	4 "

Dissolve in two to four quarts of water. When completely dissolved, dilute to 25 gallons.

With this solution every crevice, nook and corner of the house was to be carefully sprayed. Care was advised in the handling of the solution as it is highly poisonous. It would not only be found a sure way of getting rid of the mites but of all disease germs. A thorough whitewashing was then advised, as was also the removal of any lice that might be on the hens, before returning the hens again to their quarters.

The same remedy recommended, in a similar case but in a different part of the country was said to have been as successful as could be desired.

ARTIFICIAL INCUBATION.

In the month of April last an incubator of 220 egg capacity and a brooder were purchased from the Cyphers Incubator Co., of Wayland, N. Y. The incubator was placed in a small room at end of the main poultry building and the brooder on the grass in front of the house.

In the same room was a Prairie State incubator of 100 eggs capacity and another called the 'Best' from London, Ont., and of same capacity as second named. The latter seemed to have been injured in transit to such an extent that it could not hold the heat and it was not operated.

The first two attempts in early March and April with the Prairie State were not successful. In the latter case only eight chicks were hatched of which five survived and attained full growth. The eggs were tested at the proper time and the unfertile ones removed. Examination of the remaining eggs in both cases showed embryo chickens in different stages of advancement from 10th to 15th or 16th day, between which dates life seemed to have ceased. This was more noticeable in the second attempt.

Eggs which were under hens about same time as second experiment was going on and which did not hatch were examined and showed chicks also dead in the shells. This pointed to the eggs being at fault and showed the difficulty of having early fertile eggs from hens which had been confined to limited quarters and stimulated to lay during the winter months.

It was thought that the eggs from hens which had been kept under the same conditions during the winter months and only commenced to lay in late February, or

early March, would not only be more fertile, but that the germs would be stronger. But such did not seem the case. This was attributed to the long term of winter confinement in comparatively limited quarters and the stimulating rations.

Against the foregoing is the experience of three years ago, when a broody hen was set on February 20, on thirteen eggs, from a pen of Barred Plymouth Rock hens, which had laid well from November previous; were mated in early February and from which thirteen eggs, eleven lively chicks were hatched.

On one occasion four settings of eggs were obtained early in the season from a farmer, twenty miles from the city and put into an incubator. Results were same as noted above. Later eggs were obtained from leading breeders and put under hens. Results were very little different. Both from farmer and breeders the eggs had to come to the city by express and might have been to a certain extent injured in carriage. One of the breeders said his eggs were from hens which had laid all winter. On being tested, they were mostly all found unfertile.

The whole subject affords good ground for careful experimental investigation.

The Cyphers incubator was not put into operation until May 12, when 120 eggs of different breeds were put into it. Thirty unfertile eggs were tested and out of the remaining ninety fertile eggs, sixty chicks were hatched. Of this number five were weaklings and died. Later five others succumbed. The remainder made rapid and vigorous growth in the brooder. When too large for the brooder they were placed in coops in a field. From first to last their progress was satisfactory.

EXPERIMENTS IN THE PRESERVATION OF EGGS.

The following experiments, in the way of finding out the best egg preservative, made by Mr. F. T. Shutt, M.A., chemist to the Experimental Farms, will be found interesting and useful. Much inquiry is made from time to time as to the best means and methods of keeping eggs in good condition for longer or shorter periods. An important factor, sometimes overlooked, is the certainty that the eggs are strictly fresh at time of placing in the preservative. Mr. Shutt was kind enough to associate me with himself in the experimental work, and so allow me opportunity to note progress, from the inception of the different tests until their conclusion. The results are given by himself in the following pages :—

THE PRESERVATION OF EGGS.

(By Frank T. Shutt, M.A., F.I.C., F.C.S.)

In the autumn of 1898, we instituted a series of experiments to ascertain the relative value of certain solutions as egg preservatives. The eggs used in this investigation were quite fresh, being supplied by the Poultry Department of the Experimental Farm, Ottawa, and taken from the nest within a few hours, at most, of being laid. The liquids employed were (1) a saturated solution of lime-water, and (2) a ten per cent. solution of "water glass" (sodium silicate).

The eggs were treated during the first week of October, 1898, and tested March 2, 1899. Those eggs which were not kept throughout this term in either of the preservatives, together with the untreated eggs, were placed in a rack within a drawer in the laboratory. The eggs in the solutions were also in the laboratory, and consequently all were at a temperature of about 70 degrees F. throughout the winter. The examination consisted of noting the appearance on breaking and the colour, odour, taste, etc., after poaching.

TREATMENT AND RESULTS.

No. 1. *Untreated.*—The 'yolk' was stuck to the side of the shell and was much shrunken, having lost its globular form.

The 'white' had taken on a slightly yellow tint, which was more pronounced on boiling.

The 'air-space' was very large, occupying about $\frac{1}{3}$ of the shell, showing shrinkage from evaporation.

There were no signs of decay and the eggs might be pronounced as free from odour and apparently good.

On boiling, a faint "stale" odour and taste was developed.

No. 2. Kept under lime-water 2 days and then put in rack in drawer.

The yolk was not stuck to the shell and was more globular than in the untreated, though not so globular as that in the fresh egg.

The 'white' was similar to that in the untreated.

The 'air-space' was only about one half the size of that in the untreated, showing less shrinkage.

Apparently quite good, but developing a slight 'stale' odour and flavour on boiling.

No. 3. Kept under Lime Water Seven Days and then placed in rack.

Apparently quite good; somewhat less shrinkage, perhaps, of the yolk than in No. 2, but in all other particulars giving practically the same results.

No. 4. Kept in Lime-Water continuously throughout period of testing.

Apparently quite good, but the 'white,' as before, turning slightly yellow and a faint stale odour developing on boiling.

Yolk almost, or quite, globular. 'Air-space' no larger than in fresh egg.

No. 5. Kept in Silicate of Soda twenty four hours and then placed in rack.

Apparently quite good; the "white" had taken on a faint yellow tinge. Yolk slightly stuck to shell and shrunken; "air-space" larger than in Nos. 2 and 3.

On boiling, the 'white' became slightly yellower, and the 'stale' odour before mentioned was developed.

No. 6. Kept in Silicate of Soda three days and then placed in rack.

Apparently good, but yolk slightly stuck to shell. In all respects very similar to No. 5.

No. 7. Kept in Silicate of Soda seven days and then placed in rack.

Apparently good, but yolk stuck to shell. 'Air-space' somewhat similar to Nos. 5 and 6.

On boiling, was similar to Nos. 5 and 6, as to colour and odour. Shell did not break on boiling.

No. 8. Kept in Silicate of Soda continuously throughout testing period.

Apparently quite good and no shrinkage. 'Air-space' not larger than in fresh egg. Yolk globular.

On boiling, the "white," as before, assumed a faint yellowish tinge and the egg had a slight "stale" or musty flavour. Shell broke on boiling, but not so as to allow contents to escape.

CONCLUSIONS.

1. In no instance, either of treated or untreated eggs, were any 'bad' eggs found.

2. In all cases where the eggs were not kept covered with the preservative solution, shrinkage of the contents had taken place, as shown by the larger air-space and the less globular form of the yolk. The eggs treated for seven days and less with lime-water showed somewhat less shrinkage than those treated a similar length of time with silicate of soda.

3. From the experiments here recorded, it would appear that lime-water and "water glass" used continuously, as in Nos. 4 and 8, are equally efficacious in preventing shrinkage. They may also be said to have practically the same results as regards both external and internal appearances, flavour, etc., of the eggs preserved. Since silicate of soda is more costly and more disagreeable to use than lime-water, we could not from the present results recommend it as the better preservative.

4. The albumen or 'white' in all the preserved eggs was very faintly yellow (though not to the same degree in all eggs), the tint becoming deeper on boiling.

5. No offensive odour was to be perceived from any of the eggs when broken, but in all instances a faint but peculiar musty or stale odour and flavour developed on poaching.

6. It is probable that no preservative will prevent the loss of flavour possessed by the fresh egg, but those which wholly exclude the air. (and thus at the same time prevent shrinkage from evaporation) will be the most successful. Continuous submergence is evidently better than treatment for a few days.

It is, of course, essential that eggs to be preserved should be perfectly fresh when treated.

In order to learn the effect of keeping these eggs a still longer period, a number of those treated in October, 1898, were retained under their respective conditions, or in other words, the experiment was continued until December 28, 1899, a fourteen months test, when an examination was made with the following results :—

No. 1 Untreated :—Completely dried up ; the solid contents of the shell had a faint musty odour, but no marked decomposition was apparent to the eye.

No. 2 Kept under lime-water two days and preserved in rack in drawer. The "white' or albumen had taken a yellow tint, a partial drying up of contents was observed, the yolk in many cases adhering to the shell.

No. 3 Kept under lime-water seven days and preserved in rack in drawer. Nothing offensive about contents, but 'white' was discoloured and yolk slightly hardened. Not quite so much evaporation as in No. 2.

No. 4 Kept in lime-water continuously. 'White' somewhat discoloured. Yolk of normal shape and size and quite firm. Apparently in excellent state of preservation No marked odour. Poached well and quite sweet.

No. 5 Kept in silicate of soda twenty-four hours and then placed in rack. Contents completely dried up, but no offensive odour or appearance of decomposition.

No. 6 Kept in silicate of soda three days and then placed in rack. 'White' discoloured and more fluid than normal Yolk considerably hardened, faint alkaline smell. Of the four eggs tested, one was rotten ; the other, partly dried out.

No. 7 Kept in silicate of soda seven days and then placed in rack. Similar to No. 6.

No. 8 Kept in silicate of soda continuously. Further trials, using other fluids were commenced in June of this year. The examination of the eggs was made on December 28, with the following results :—

Common salt, 10 per cent solution.—'White' quite limpid, yolk reduced in size, hardened, turned red and globular. Contents had an unpleasant smell ; the boiled eggs tasted distinctly of salt. The eggs had materially increased in weight, owing to absorption of salt.

Lime-water and 10 per cent solution of common salt.—External appearance good. 'White' or albumen slightly discoloured. Poached egg had very fair taste with a suspicion of salt.

Saturated Lime-water.—Eggs placed in solution June 9, 1899. Excellent external appearance. No appreciable change in weight. Contents: 'white' only slightly tinted, no smell; on poaching, quite eatable, though not equal in flavour to fresh egg.

Coated with paraffin and kept in bottle.—Dipped momentarily in melted paraffin on June 26, 1899. Eggs coated thickly with mould. Albumen quite fluid. Yolk turned greenish-white; very offensive; thoroughly bad.

Glycerine 5 per cent.—Immersed continuously since June 5, 1899. Very offensive smell to both eggs and fluid. Contents of egg entirely fluid and badly decomposed.

Glycerine 10 per cent.—Immersed continuously since June 5, 1899. Contents quite fluid with very offensive smell.

Distilled water.—Immersed continuously since June 26, 1899. Floating, slimy matter in fluid and covering the eggs. Three of the four eggs under trial were bad, contents being very offensive.

Conclusions.—This further investigation strongly confirms the results obtained with the first series of experiments as regards the value of saturated lime-water as an egg preservative. As far as our experience goes, no other fluid is its equal, the eggs from this preservative being far and away superior to those kept by the other methods here stated.

STATEMENT OF EXPENDITURE ON THE DOMINION EXPERIMENTAL FARMS FOR THE YEAR ENDING JUNE 30, 1899.

CENTRAL EXPERIMENTAL FARM—EXPENDITURE, 1898-9.

Live stock	$ 861 95
Feed for stock, including veterinary services	373 82
Seed grain, seeds, trees, &c.	668 30
Implements, tools, hardware and supplies	1,114 71
Drainage and drain tiles	6 25
Manure and fertilizers	270 56
Travelling expenses	1,144 66
Exhibition expenses	356 91
Blacksmithing, harness supplies and repairs	465 08
Bee department	194 82
Salaries	1,860 00
Wages, farm work, including experimental work with grain and other farm crops; also, salaries of officers in charge	6,097 83
Wages, care of stock	2,498 75
Chemical department proportion chargeable to the Central Farm	864 73
Botanical and Entomological department proportion chargeable to the Central Farm	1,109 24
Horticultural department, including salary of officer in charge	3,745 48
Poultry department, including salary of officer in charge	1,600 44
Forestry department and care of grounds	643 56
Arboretum	564 35
Distribution of trees and tree seed	64 36
Office help, correspondence branch and messenger service	3,415 97
Printing and stationery	781 30
Seed testing and care of greenhouses	866 64
Dairy department	500 23
Museum	14 35
Contingencies, including services and expenses of L. V. Labelle delivering lectures and giving instruction on tobacco culture, $448.86; gravelling roads through farm, $532.97; cutting, drawing and packing ice, $66.95; sewers, $39.37	1,618 70
Books and newspapers	176 99
Telegrams and telephones	136 13

APPENDIX

TO THE

REPORT OF THE MINISTER OF AGRICULTURE

ON

EXPERIMENTAL FARMS

OTTAWA, December 1, 1900.

SIR,—I beg to submit for your approval the fourteenth annual report of the work done, and in progress, at the several experimental farms.

In addition to my report, you will find appended, reports from the following officers of the Central Experimental Farm : From the Agriculturist, Mr. J. H. Grisdale ; from the Horticulturist, Mr. W. T. Macoun ; from the Chemist, Mr. Frank T. Shutt, and from the Entomologist and Botanist, Dr. James Fletcher. A report is also submitted from the Poultry Manager, Mr. A. G. Gilbert.

From the Branch Experimental Farms there are reports from Mr. R. Robertson, Superintendent, and from Mr. W. S. Blair, Horticulturist of the Experimental Farm for the Maritime Provinces, at Nappan, Nova Scotia; from Mr. S. A. Bedford, Superintendent of the Experimental Farm for Manitoba, at Brandon ; from Mr. Angus Mackay, Superintendent of the Experimental Farm for the North-west Territories, at Indian Head, and from Mr. Thos. A. Sharpe, Superintendent of the Experimental Farm for British Columbia, at Agassiz.

In these reports there will be found the results of many important and carefully conducted experiments in agriculture, horticulture and arboriculture, the outcome of practical work in the fields, barns, dairy and poultry buildings, orchards and plantations at the several experimental farms ; also of scientific investigations in the chemical laboratory and the information gained from the careful study of the life histories and habits of injurious insects and the methods by which noxious weeds are propagated and spread, together with the most practical and economical measures for their destruction. In the report of the Entomologist and Botanist will also be found particulars of the experiments and observations which have been made during the past year in connection with the Apiary.

The large and constantly increasing demand by the farmers of the Dominion for the publications issued from the experimental farms is a gratifying evidence of the desire for information among this class of the community, also of the high esteem in which these records of the work of the farms are held. It is hoped that the facts brought together in the present issue will be found of much practical value to the Canadian farmer and fruit-grower and that they may assist in advancing agriculture and horticulture in this country.

I have the honour to be, sir,
Your obedient servant,

WM. SAUNDERS,
Director Experimental Farms.

To the Honourable
The Minister of Agriculture,
Ottawa.

ANNUAL REPORT

ON THE

EXPERIMENTAL FARMS

REPORT OF THE DIRECTOR, WM. SAUNDERS, LL.D., F.R.S.C., F.L.S.

In submitting the fourteenth annual report giving particulars of some of the operations conducted on the five experimental farms established by the Dominion Government for the benefit of farmers residing in the different climates of Canada, it is hoped that the facts presented, which are the results of careful observation and experiment, will be found of much practical utility.

The reports of the several officers engaged in the different lines of work contain much information on a variety of subjects, all bearing on practical agriculture or horticulture. The best methods of maintaining the fertility of the land, and of economizing the fertilizers produced on the farm, the most useful measures to adopt in preparing the land for crop, how and when seed should be sown, and which are the varieties which experience has shown to be the best and most productive, are all referred to. Much information is also given as to the care of cattle, swine, sheep and poultry and the most economical and profitable methods to adopt in the feeding and breeding of these different classes of stock for the production of meat, dairy products and eggs. The growing of all the different classes of fruit and vegetables has received much attention and lists have been prepared of varieties found specially suitable to certain localities and climates with particular reference to the needs of farmers. The selection and care of the many different sorts of useful timber and ornamental trees adapted to Canada has received much attention, embracing such varieties as are specially suitable for shelter belts and others adapted for the beautifying of homes.

The subjugation of insect pests and noxious weeds has claimed close observation and study, so also have the many chemical problems which present themselves in connection with agricultural pursuits, the solution of which is most important to success. These with many other useful subjects are under constant investigation and experiment. By the use of such information presented from year to year, improvements have taken place in farm life, leading to the avoidance of waste, and to economy in production, with increased profits as the result.

The interdependence of all branches of farm work and a knowledge of how these can best be carried on in conjunction so as to produce the most satisfactory returns under the varied conditions which surround the settler in different parts of the Dominion, are items of information of deep interest to farmers everywhere. The days are passing by when farmers will rest satisfied with the risky position of depending entirely on one crop. With adverse seasons, which occur more or less often in almost

every country, such men on such occasions lose ground financially, and sometimes to such an extent as to take them several years to recover. The best and happily the system most generally followed now is mixed farming. This is eminently adapted to all parts of Canada, and to the rapid growth of this system of diversified agriculture may be attributed much of the phenomenal increase in the exports of Canadian agricultural products, which has taken place during the past ten or twelve years.

During the past season the writer has had an opportunity of visiting Great Britain and France, and of noting the progress of agriculture there, and the results produced by the measures which have been adopted to assist farmers in their work, further particulars of which will be found in another part of this report. The experience gained but strengthens the opinion that Canadian farmers are well to the front in almost everything, and that there is no other country where there are so many useful measures in operation designed to assist the farmer in overcoming the difficulties he has to contend with, and to aid him in his endeavours to acquire a better practical knowledge of the important principles which underlie his useful occupation. It is gratifying to know that the farmers of this country are eager for information and always ready to take advantage promptly of every opportunity of improving their condition. With such a spirit of enterprise abroad and the enormous agricultural resources awaiting development in Canada, the future prosperity of the country is assured.

This fourteenth annual report of the work of the experimental farms is submitted to the farmers of Canada with the earnest hope that it may prove helpful to them in the great work they have in hand of advancing the agricultural interests of this country.

EXPERIMENTAL WORK

CONDUCTED AT THE CENTRAL EXPERIMENTAL FARM, OTTAWA, ONTARIO.

EXPERIMENTS WITH OATS.

Eighty-two varieties of oats have been under trial in the uniform test plots at the Central Experimental Farm during 1900. These experiments have been conducted in all cases to gain information as to the relative productiveness, earliness and other characteristics of the different sorts. The soil on which these oats were sown was a sandy loam which received a dressing of barn-yard manure during the winter of 1898-9 of about 12 tons per acre. The previous crop was turnips. After the turnips were taken off the land was drilled up in ridges 2½ feet apart and left in this condition until the following spring, when it was cultivated twice with a two-horse cultivator and twice with a smoothing harrow. The seed of all the varieties was sown on May 4, on plots of one-fortieth of an acre each, seed being used in each case at the rate of 2 bushels per acre. Among the varieties tested this year were the following thirteen cross-bred sorts, all of which have been originated on the experimental farms:—Holland, Cromwell, Olive, Oxford, Pense, Miller, Brandon, Milford, King, Medal, Kendal, Master and Russell. Waverley and Tartar King are two new cross-bred oats recently introduced by Garton Bros., of Newton le Willows, England. Longhoughton is a favourite Scotch variety, and Anderbecker, Leutewitzer, Selchower and Uberfluss have been received for test from Germany.

EXPERIMENTS WITH OATS GROWN AFTER DIFFERENT CROPS.

During the past season six plots, one-fortieth acre each, have been used in this test to ascertain what effect different crops have on the soil they are sown upon, and how far they influence a subsequent oat crop. The soil in this instance was a sandy loam of good quality. After the crops were taken off last autumn, the land was gang-ploughed shallow, and later in the fall it was ploughed to the depth of about 7 inches. In the spring of 1900 it was harrowed twice with disc-harrow and twice with smoothing harrow, and all sown with Sensation oats at the rate of 2 bushels per acre on May 4. They were cut on August 14, with the following results:—

Previous Crop in 1899.	Sensation Oats in 1900 Yield per acre.		Length of Straw.	Length of Head.
	Bush.	lbs.	Inches.	Inches.
Plot 1 Flax	49	14	40—45	8—9½
Plot 2 Grain	58	28	43—48	8½—9½
Plot 3 Horse Beans	69	14	46—50	9—10
Plot 4 Soja Beans	49	14	40—45	8½—9½
Plot 5 Corn	52	32	40—45	8½—9½
Plot 6 Millet	43	18	36—40	7¾—8½

EXPERIMENTS WITH BARLEY.

Fifty-nine varieties of barley have been under test in the uniform trial plots for 1900. Twenty-four of these have been two-rowed sorts and thirty-five six-rowed. The land chosen for the barley plots was a heavy sandy loam, mixed with clay. The previous crop was clover hay. The land was ploughed late in the autumn to the depth of about 7 inches and left in that condition until the following spring, when it was harrowed twice with the disc-harrow and twice with the smoothing harrow before sowing. The size of the plots was one-fortieth of an acre each, and they were all sown on May 1, the two-rowed at the rate of 2 bushels per acre and the six-rowed at the rate of 1¾ bushels per acre. The seed of all these varieties of barley, both two-rowed and six-rowed, was obtained from selected heads picked carefully by hand, the largest and plumpest being chosen.

Among the varieties tested this year are the following hybrid sorts, all of which have been produced at the experimental farms:—Sixteen two-rowed barleys: Beaver, Bolton, Gordon, Jarvis, Clifford, Harvey, Dunham, Victor, Nepean, Fulton, Sidney, Logan, Pacer, Leslie, Monck and Rigid, and twenty-one six-rowed sorts, namely: Pioneer, Royal, Argyle, Summit, Albert, Vanguard, Claude, Surprise, Success, Nugent, Trooper, Mansfield, Stella, Garfield, Empire, Phœnix, Yale, Brome, Parkin, Munro and Lytton. The last four named are new hybrids which have been introduced this year. The following is their parentage:—

No. 18. Parkin Beardless—Royal, six-rowed bearded female; Success, six-rowed beardless male.

No. 19. Munro Bearded—Royal, six-rowed bearded female; Success, six-rowed beardless male.

No. 20. Lytton—Royal, six-rowed female; Beaver, two-rowed male.

No. 21. Pelham—Royal, six-rowed female; Beaver, two-rowed male.

Royal, the female parent of Parkin and Munro, is a hybrid between a two-rowed barley, known as Swedish, and a plump six-rowed variety, known as Baxter. Success is a beardless barley. One of the crosses, Parkin, is beardless, like the male parent; the other is bearded and resembles Royal.

In the third case, Lytton is a cross with Royal six-rowed and Beaver two-rowed. Beaver was one of the earlier hybrids, the result of a cross between a two-rowed sort (Swedish) and a six-rowed Baxter. In this case, although in parentage it is two-thirds two-rowed, this barley is, nevertheless, a six-rowed sort. Pelham is a two-rowed sort. The three parents of these hybrids have been very productive.

Nos. 18 and 19 are crosses which were made by the present Horticulturist of the Central Experimental Farm, Mr. W. T. Macoun, in 1895. Nos. 20 and 21 are the work of Dr. C. E. Saunders, in 1896.

BARLEY GROWN FROM SCREENED SEED.

While all the uniform trial plots of barley were grown, as already stated, from seed obtained from carefully selected heads, the seed of the following ten varieties was not from selected heads. After the barley plots were threshed, the grain for this purpose was passed through the fanning mill to take out the small kernels, and the clean, plump seed remaining was saved.

Six of these varieties were six-rowed and four were two-rowed, and the following are the results. It will be seen that in every instance but one the seed from selected heads has given the larger crops, the increase per acre varying from 40 pounds to 8 bushels and 40 pounds. The one exception was a two-rowed sort, the Danish Chevalier, which gave a crop of 2 bushels 24 pounds less per acre from the selected heads. These were all sown on the same day as the uniform trial plots, May 1; the plots were adjoining, with similar soil and similarly treated, the size in each case being one-fortieth of an acre.

RESULTS of sowing Screened Seed compared with Selected.

FORMALIN AND MASSEL POWDER AS PREVENTIVES OF SMUT IN OATS AND BARLEY.

Three varieties of grain were used in this experiment, viz.: Doncaster Prize oats and Odessa and Canadian Thorpe barleys. These were all sown on May 23, in plots 33 feet long, in rows 9 inches apart; four rows in each test, the heads of which were counted when the smut was fully advanced. The grain used for seed in each case was quite smutty.

EXPERIMENTS WITH FALL WHEAT.

The number of varieties of fall wheat under trial during the past season was twenty-two. Their names were as follows:—Poole, Gold Coin, Dawson's Golden Chaff, Bonnell, Standard, Winter King, Early Ripe, Red Velvet Chaff, Jones' Winter Fife, Pride of Illinois, American Bronze, Early Red Clawson, Russian Amber, Long Berry Red, Early Gennessee Giant, Buda Pesth, Reliable, Golden Cross, Imperial Amber, Tasmania Red, Egyptian and Velvet Chaff. These were all sown in plots of one-fortieth acre each, on September 13, 1899. The winter was unfavourable for this crop, and in the spring of 1900 all the plots were found to be so badly winter-killed that they were not worth leaving, and were ploughed under.

EXPERIMENTS WITH SPRING WHEAT.

Seventy-two varieties of spring wheat have been tested in the uniform trial plots during the past season. The soil was a heavy sandy loam of fairly good quality, slightly mixed with clay, which received a dressing of about 15 tons of barn-yard manure per acre in the spring of 1897. No fertilizer has been applied since. The previous crop was hay. The land was ploughed late in the autumn to the depth of about seven inches, and left in that state until the following spring, when it was harrowed twice with the disc-harrow and twice with the smoothing harrow before sowing. The size of the plots was one-fortieth acre each; they were all sown on April 28, using at the rate of one bushel and a half of seed per acre.
